EDITORS IN CHIEF

Dennis H. Bamford, PhD, is Professor Emeritus of Virology at the Faculty of Biological and Environmental Sciences, University of Helsinki, Finland. He obtained his PhD in 1980 from the Department of Genetics, University of Helsinki. During 1981–1982 he was an EMBO postdoctoral fellow at the Public Health Research Institute of the City of New York, United States, and during 1983–1992 he worked as a Senior Scientist at the Academy of Finland. In 1993 he was appointed Professor of General Microbiology at the University of Helsinki. He was awarded the esteemed Academy Professorship twice, in 2002–2007 and 2012–2016, and he also served twice as the Director of the Finnish Center of Excellence (in Structural Virology, 2000–2005, and in Virus Research, 2006–2011). Prof. Bamford has had continuous external research funding (e.g., from several European Union, Academy of Finland, TEKES and Jusélius Foundation funds, as well as the Human Frontier Science Program). He is an EMBO member and has held several positions of trust in scientific and administrative organizations.

Prof. Bamford has published approx. 400 articles in international peer-reviewed journals in virology, microbiology, biochemistry, and molecular biology (36 of them in high impact journals). About half of the primary articles have been published with international collaborators showing high international integration. He has also been invited to give 56 keynote and plenary presentations in major international meetings. Prof. Bamford has supervised over 35 Master's and

over 40 PhD theses. Seven of his graduate students or post docs have obtained a professorship and a similar number have a principal investigator status. Prof. Bamford has studied virus evolution from a structure-centered perspective, showing that seemingly unrelated viruses, such as bacteriophage PRD1 and human adenovirus have similar virion architecture. When the corona virion architecture was gradually revealed, it was observed that its structural elements were close to those seen in RNA bacteriophage phi6 so that phi6 has been actively used as surrogate for pathogenic viruses - quite a surprise!

Dr. Mark Zuckerman is Head of Virology, Consultant Medical Virologist, and Honorary Senior Lecturer at South London Specialist Virology Centre, King's College Hospital NHS Foundation Trust and King's College London Medical School, Department of Infectious Diseases, School of Immunology and Microbial Sciences in London, United Kingdom. His interests include the clinical interface between developing molecular diagnostic tests relevant to the local population of patients, respiratory virus infections, herpesvirus infections in immunocompromised patients and blood-borne virus transmission incidents in the healthcare setting. He has chaired the UK Clinical Virology Network, Royal College of Pathologists Virology Specialty Advisory Committee and Virology Examiners Panel and is a member of the Specialty Advisory Committee on Transfusion Transmitted Viruses. He is a co-author on four editions of the "Mims' Medical Microbiology" textbook, has written chapters in a number of other textbooks and has over 100 publications in international peer-reviewed journals and is an associate editor for two journals.

SECTION EDITORS

Claude Fauquet received his PhD in biochemistry from University Louis Pasteur in Strasbourg, France in 1974. Dr. Fauquet joined the Institut de Recherche pour le Développement (IRD) and worked there as a plant virologist for 28 years, and served in Ivory Coast, West Africa for 14 years. In 1991, he founded the International Laboratory for Tropical Agricultural Biotechnology (ILTAB) at The Scripps Research Institute, CA, United States. ILTAB was then hosted by the Donald Danforth Plant Science Center, St. Louis, MO, from 1999 to 2012. In 2003, he co-founded the Global Cassava Partnership for the 21st Century (GCP21), which he directed until 2019 and which goal is to improve the cassava crop worldwide.

Dr. Fauquet is an international leader in plant virology including taxonomy, epidemiology, molecular virology, and in gene-silencing as an antiviral strategy. He was Secretary of the International Committee on Taxonomy of Viruses (ICTV) for 18 years and the editor of several ICTV Reports including the VIIIth ICTV Report in 2005.

He has published more than 300 research papers in reviewed journals and books. He is a fellow of the American Association for the Advancement of Science, of the American Phytopathological Society and a member of the St. Louis Academy of Sciences. In 2007, Dr. Fauquet was knighted “Chevalier de l’Ordre des Palmes Académiques” by the French Minister of High Education and Research.

Dr. Michael Feiss is Professor Emeritus in the Department of Microbiology and Immunology of the Carver College of Medicine at the University of Iowa, IA, United States. Dr. Feiss received his PhD in Genetics at the University of Washington followed by a postdoctoral traineeship in the laboratory of Dr. Allan Campbell at Stanford. Dr. Feiss is a microbial geneticist who studies virus assembly with an emphasis on how a DNA virus, bacteriophage lambda, packages viral DNA into the empty prohead shell. The lab investigates how sites in the viral DNA orchestrate the initiation and termination of the DNA packaging process. This work includes comprehensive examination of the DNA recognition sites. A related interest is study of terminase, the viral DNA packaging enzyme, including the functional domains for protein–DNA and protein–protein interactions. A second focus has been the roles of the bacterial host’s IHF and DnaJ proteins in the lytic life cycle of the virus. More recent work has involved a genetic dissection of the role of terminase’s ATPase center that powers translocation of viral DNA into the prohead. This interest in the ATP hydrolysis-driven packaging motor involves a multidisciplinary collaboration examining the kinetics of DNA packaging during individual packaging events. Finally, recent studies have also looked at how the packaging process has diverged among several lambda-like phages, including phages 21, N15, and Gifsy-1.

Elizabeth E. Fry is a senior postdoctoral scientist in structural biology at the University of Oxford, Oxford, United Kingdom, where she received her DPhil. for studies relating to the structure determination of Foot-and-Mouth Disease Virus. Specializing in structural virology, Dr. Fry has studied many virus/viral protein structures but her primary focus is on picornavirus structure and function, in particular receptor interactions and virus uncoating. She is particularly interested in rationally designing virus-like-particles as next generation vaccines to reduce the inherent risks in handling live viruses.

Said A. Ghabrial[†] received his BSc in 1959 from Cairo University, Cairo, Egypt, and his PhD from Louisiana State University, Baton Rouge, LA, United States, in 1965. Dr. Ghabrial did postdoctoral research at the University of California, Davis, CA, United States, before returning to Cairo, where he served as a plant virologist in the Ministry of Agriculture. He returned to the United States in 1970 to do postdoctoral research at Purdue University, West Lafayette, IN. In 1972, he joined the Plant Pathology Department at the University of Kentucky, Lexington, KY, United States, where he rose to the rank of professor in 1986 and worked until 2013.

Dr. Ghabrial has served as an associate and senior editor of *Phytopathology*. He served on the editorial boards of the *Encyclopedia of Virology*, 3rd edition and *Encyclopedia of Plant Pathology*, and edited a thematic issue of *Advances in Virus Research* on "Mycoviruses". He was a member of the American Phytopathological Society (APS) and the American Society for Virology (ASV); in July 2002 he was elected as a Fellow of the American Phytopathological Society. He also acted as Chair of the ICTV Subcommittee on Fungal Viruses in 1987–1993 and 2011–2014.

His long professional career allowed him to make many scientific achievements in phytopathology and virology. Among them are molecular dissection of a legume-infecting RNA virus, bean pod mottle virus (BPMV), development of BPMV-based vectors, discovery of a transmissible debilitation disease of the phytopathogenic ascomycete, *Helminthosporium victoriae* (*Cochliobolus victoriae*), establishment of a viral etiology of the *H. victoriae* disease, and advancement of structural biology of diverse fungal viruses.

Eric Hunter, PhD, is Professor of Pathology and Laboratory Medicine at Emory University, Atlanta, GA, United States. He serves as Co-Director of the Emory Center for AIDS Research and is a Georgia Research Alliance Eminent Scholar.

Dr. Hunter's research focus has been the molecular virology and pathogenesis of retroviruses, including human immunodeficiency virus. He has made significant contributions to the understanding of the role of retroviral glycoprotein structural features during viral entry and providing unique insights into the assembly and replication of this virus family. In recent years the emphasis of his research has been on HIV transmission and pathogenesis, defining the extreme genetic bottleneck and selection of viruses with unique traits during HIV heterosexual transmission. He has described the selection of fitter viruses at the target mucosa, a gender difference in the extent of selection bias, and a role for genital inflammation in reducing selection. His research has defined the impact of HIV adaptation to the cellular immune response on immune recognition and control of HIV after

transmission, as well as on virus replicative fitness in vitro and in vivo. Recent work highlights the roles that virus replicative fitness and sex of the host play in defining disease progression in a newly infected individual. His bibliography includes over 300 peer-reviewed articles, reviews, and book chapters. He has also been the recipient of four NIH merit awards for his work on retrovirus and HIV molecular biology.

Dr. Hunter served as the Editor in Chief of the journal *AIDS Research and Human Retroviruses* for 10 years. He was Chair of the AIDS Vaccine Research Subcommittee which is charged with providing advice and consultation on AIDS vaccine research to the National Institute of Allergy and Infectious Diseases and continues to serve on editorial boards for several academic journals and on external advisory committees for several government, academic, and commercial institutions.

Ilkka Julkunen graduated as an MD/PhD in 1984 from the Department of Virology, University of Helsinki, Helsinki, Finland. He worked as a postdoctoral research fellow at Memorial Sloan-Kettering Cancer Center in New York, United States, in 1986–1989, followed by positions as a senior scientist, group leader and research professor at Finnish Institute for Health and Welfare in 1989–2013. In 2013 he became a Professor of Virology at the University of Turku, Turku, Finland. The research interests of Dr. Julkunen have concentrated on innate and adaptive humoral immunity in viral and microbial infections. He has studied intracellular signaling and RIG-I and TLR-mediated activation of interferon system in human macrophages and dendritic cells and stable cell lines in response to human and avian influenza, Sendai, Zika and coronavirus infections. In addition, he has analyzed the downregulation of innate immunity by viral regulatory proteins from influenza, HCV, flavi-, filo- and coronaviruses. He has expertise in vaccinology, biotechnology and development of methods to analyze antiviral immunity, he has also been actively involved in research training and collaborations with biotechnological industry.

[†]Deceased.

Peter Krell started his career in virology early as a summer high school student working for the Canadian Forestry Service studying the resistance of nuclear polyhedrosis viruses (now called baculoviruses) to environmental exposure with Dr. Fred T. Bird at the Insect Pathology Research Institute in Sault Ste. Marie, ON, Canada. He received his BSc and MSc in biology from Carleton University studying the iridovirus *Tipula Iridescent Virus* with Dr Peter Lee, in Ottawa, the Canadian capital. For his PhD he headed east to Dalhousie University in Halifax, Nova Scotia on the Atlantic coast. In addition to enjoying the salt sea air, fresh cod, lobster and mussels, he studied the molecular biology of polydnaviruses under the guidance of Dr Don Stoltz. Heading south to Texas A&M University in College Station, TX, United States, as a Postdoctoral Fellow he worked with Dr. Max Summer, of baculovirus fame, and Dr. Brad Vinson continuing to study polydnaviruses, but also became steeped in the early days of molecular baculovirology. He then accepted a faculty position in the Department of Microbiology and Immunology at the University of Guelph in Guelph, ON, Canada. There he switched to baculovirus research, which was more tractable, due in part to available cell cultures and focused on viral DNA replication and functional genomics,

particularly on chitinase, cathepsin and ME53. In collaboration with Dr. Eva Nagy he studied molecular biology of different animal viruses, notably Fowl Avian adenoviruses and their development as vaccine vectors, but also on the birnavirus infectious pancreatic necrosis virus, the coronavirus porcine endemic diarrhea virus, fowlpox virus and the paramyxovirus Newcastle disease virus. He has been involved extensively with virus taxonomy, being active in the International Committee on Taxonomy of Viruses (ICTV) as member of the *Polydnaviridae* and *Baculoviridae* study groups, national representative of Canada on the ICTV, member of the Executive Committee for the ICTV and Chair of the ICTV Invertebrate Virus Subcommittee. In terms of governance, Peter Krell was President of the Canadian Society of Microbiology, Secretary and later President of the Society for Invertebrate Pathology, as well as being on the Editorial Boards of the *Canadian Journal of Microbiology* and the *ASM Journal of Virology*. While at the University of Guelph, he rose through the ranks to Professor and is currently University Professor Emeritus.

Mart Krupovic is the Head of the Archaeal Virology Unit in the Department of Microbiology at the Institut Pasteur of Paris, France. He received his MSc in Biochemistry in 2005 from the Vilnius University, Vilnius, Lithuania and PhD in 2010 in general microbiology from the University of Helsinki, Helsinki, Finland. His current research focuses on the diversity, origin, and evolution of viruses, as well as molecular mechanisms of virus–host interactions in archaea. He has published over 170 journal articles and serves as an editor or on the editorial boards of *Biology Direct*, *Research in Microbiology*, *Scientific Reports*, *Virology*, and *Virus Evolution*. He is also a member of the Executive Committee of the International Committee on Taxonomy of Viruses (ICTV) and chairs the Archaeal Viruses Subcommittee of the ICTV.

Maija Lappalainen, MD, PhD, Associate Professor of Clinical Microbiology, is the Head of Clinical Microbiology in the HUS Diagnostic Center, HUSLAB, University of Helsinki and Helsinki University Hospital, Helsinki, Finland. In her thesis during the years 1987–1992 she studied the incidence and diagnostics of congenital toxoplasmosis. After PhD, her research interest has been in diagnostic clinical virology, viral hepatitis, respiratory infections, viral infections in the immunocompromised patients and viral infections during pregnancy.

Hubert G.M. Niesters (1958) studied biology and chemistry in Nijmegen, the Netherlands. After obtaining his PhD in Utrecht (Prof. dr. M. Horzinek and Prof. dr. B. van der Zeijst, 1987) on the molecular epidemiology of infectious bronchitis virus, he worked as a post-doctoral fellow with Prof. dr. Jim Strauss at the California Institute of Technology (Pasadena, United States) on the replication of Alphaviruses. He received a Niels Stensen fellowship (The Netherlands) and an E.S. Gosney fellowship (Caltech) during this period.

After returning to the Netherlands (1989), he became a research associate in medical microbiology at the Diagnostic Medical Center (Delft) but moved back to clinical virology as a senior research associate in 1991 at the Erasmus University Medical Center Rotterdam (Head Prof. dr. Ab Osterhaus). From 1993 to 2007, he was responsible for the molecular diagnostics unit. During this period, he was involved in the discovery and characterization of several new viruses and variants. In 2007, he became full professor and director of the Laboratory of Clinical Virology within the Department of Medical Microbiology at the University Medical Center Groningen and University of Groningen.

He has been actively involved in the implementation and development of new technologies like real-time amplification and automation within clinical virology. He has been focusing on molecular diagnostics and its use and the clinical value in a transplant setting, as well as in monitoring treatment of hepatitis viruses. Recently, his interest focuses on rapid regional epidemiology, automation including MiddleWare solutions for molecular diagnostics, as well as the cost-benefit of rapid point-of-impact molecular testing. Special interest is focused on raising awareness for the detection of enteroviruses (enterovirus D68) and its relationship with acute flaccid myelitis (AFM).

Since 2017, he is the Chair of the executive board of QCMD (Quality Control of Molecular Diagnostics, Glasgow). He is an auditor and team leader for the Dutch Council of Accreditation and Co-Editor in Chief of the *Journal of Clinical Virology*. He is an (co)-author of more than 250 peer-reviewed papers, chapters and reviews including emerging viruses, such as enterovirus D68 and hepatitis E virus (H-index 80).

For his entire work, he received in 2016 the “Ed Nowakowski Senior Memorial Clinical Virology Award” from the Pan American Society for Clinical Virology.

Massimo Palmarini is the Director of the MRC-University of Glasgow Centre for Virus Research and Chair of Virology at the University of Glasgow, Glasgow, United Kingdom. A veterinarian by training, his research programs focus on the biology, evolution and pathogenesis of arboviruses and the mechanisms of virus cross-species transmission. His work is funded by the MRC and the Wellcome Trust. Massimo Palmarini has been elected Fellow of the Academy of Medical Sciences, of the Royal Society of Edinburgh and of the Royal Society of Biology and he was a Wolfson-Royal Society Research Merit Awardee. He is a Wellcome Trust Investigator.

David Prangishvili, PhD, Honorary Professor at the Institut Pasteur, Paris, France, and Professor at Tbilisi State University, Tbilisi, Georgia, is one of the pioneers in studies on the biology of Archaea and their viruses. His scientific career spans ex-USSR (Institute of Molecular Biology, Moscow; 1970–1976), Georgia (Georgian National Academy of Sciences, Tbilisi; 1976–1991), Germany (Max-Planck Institute for Biochemistry, Munich; University of Regensburg; 1991–2004) and France (Institut Pasteur, Paris, 2004–2020). In the research groups headed by him, several dozens of new species and eight new families of archaeal viruses have been discovered and characterized, which display remarkable diversity of unique morphotypes and exceptional genome contents. The results of his research contribute to the knowledge on viral diversity on our planet and change the field of prokaryotic virology, leading to the notion that viruses of

hyperthermophilic Archaea form a particular group in the viral world, distinctive from viruses of Bacteria and Eukarya, and to the recognition of the virosphere of Archaea as one of the distinct features of this Domain of Life. David Prangishvili is a member of the Academia Europaea, the European Academy of Microbiology, and the Georgian National Academy of Sciences.

David I. Stuart is MRC Professor of Structural Biology in the Nuffield Department of Medicine, Oxford University, Oxford, United Kingdom, Life Science Director at Diamond Light Source and Director of Instruct-ERIC (pan-European organisation providing shared access to infrastructure and methods for structural biology). He has diverse interests in structural virology from picornaviruses, double-stranded RNA viruses and enveloped RNA viruses. His drive to develop structural techniques led to the determination of the structure of Bluetongue virus (1995) and then the first membrane containing virus, PRD1. More recently, he has been at the fore-front of bringing Cryo-EM technology to bear on virus structure determination and its future role in visualizing virus function in cellulo. In addition to basic science he has a strong commitment to structural vaccinology and the development of antiviral drugs.

Dr. Nobuhiro Suzuki, PhD, received his MSc (1985) in phytopathology and PhD (1989) in virology from Tohoku University in Sendai, Japan. Dr. Suzuki currently serves as a full Professor of the Institute of Plant Stress and Resources, formerly Institute of Plant Sciences and Bioresources at Okayama University and as an Editor of *Virus Research*, *Frontiers in Virology*, *Journal of General Plant Pathology*, *Virology Journal*, and *Biology*. He has also been Guest Editor to *PLoS Pathogens*, *PNAS*, and *mBio*, and an Editorial Board member of *Virology* and *Journal of Virology*.

Suzuki Laboratory focuses on characterization of diverse viruses infecting phytopathogenic fungi and exploration of their interplays. Recent achievements include the discovery of a neo-virus lifestyle exhibited by a (+)ssRNA virus and an unrelated dsRNA virus in a plant pathogenic fungus and of multilayer antiviral defense in fungi involving Dicer. Prior to coming to Kurashiki, Okayama Prefecture, he was a visiting fellow of the Center for Agricultural Biotechnology at the

University of Maryland Biotechnology Institute (UMBI), College Park, MA, United States, for 4 years (1997–2001) to study molecular biology of hypoviruses in the laboratory of Professor Donald L. Nuss. Before visiting UMBI, he served as an assistant professor and a lecturer of the Biotechnology Institute at the Akita Prefectural College of Agriculture, Japan, for 11 years (1988–1998) where he was engaged in a project on molecular characterization of rice dwarf phytovereovirus, a member of the family *Reoviridae*. He received awards from the Japanese Phytopathological Society of Japan and Japanese Society for Virology for his outstanding achievements in plant and fungal virology.

FOREWORD

I am delighted to write the foreword to this wonderful Fourth Edition of the *Encyclopedia of Virology*. The Third Edition was published in 2008, how the world has changed in the intervening years. The release of the updated fourth edition could not be more timely or more prescient. It is superb and a huge tribute to the authors, Elsevier the publisher, and to the brilliant editors, Dennis Bamford and Mark Zuckerman.

SARS-CoV-2 has dominated the world since it emerged in 2019 and affected every continent and every aspect of life. A reminder, if it were needed, of the impact of infectious diseases, the importance of virology and the vulnerability and interconnectivity of our world.

There is no doubt that with rapidly changing ecology, urbanization, climate change, increased travel, and fragile public health systems, epidemics and pandemics will become more frequent, more complex and harder to prevent and contain. Most of these epidemics will be caused by viruses, those we know about and maybe able to predict and some we do not know of that will emerge from animals, plants or the environment. Our changing climate will change the epidemiology of viruses, their vectors and the infections they cause, hence the critical importance of this totally revised Fourth Edition of the *Encyclopedia of Virology* which brings together research and an understanding of viruses in animals, plants, bacteria and fungi, the environment, and among humans. Never has a holistic, one-health understanding been more important.

That starts with an understanding of the fundamentals of virology, a field of science that has been transformed in the years since the Third Edition. An understanding transformed by embracing traditional fields of molecular and structural biology, genomics, and influenced by immunology, genetics, pharmacology and increasingly by epidemiology and mathematics. Events of 2020 and 2021 also show why it is so important to integrate within traditional virology an understanding of the animal and human health and behavior, of climate change and its impact on the ecology of viruses, plant sciences and vectors. And why we must understand the viruses we think we know well, and those viruses less extensively studied. Research is critical to this, research that pushes the boundaries of what we know, has the humility to seek answers to things we do not understand and shares that knowledge with the widest possible community. That research will be most exciting at the interface between disciplines, most impactful when dynamic, open, inclusive, global, and collaborative.

This is what the Fourth Edition of the *Encyclopedia of Virology*, the largest reference source of research in virology sets out to achieve. It is a wonderful contribution to a critical field of knowledge. It contains new chapters, every chapter revised and updated by a dedicated global community who have come together to provide what is a brilliant and inspiring reference. It is an honor to contribute in a very small way to the timely release of the Fourth Edition of the *Encyclopedia of Virology*.

Jeremy Farrar

PREFACE

The fourth edition of the Encyclopedia of Virology is encyclopedic, but we wanted to move away from an alphabetical list, apart from where it was more logical, to a vision that encompassed a different structure. Articles describing novel trends as well as original discoveries in specific subfields of virology have been distributed into a set of five volumes, namely Fundamentals of Virology, Human and Animal Viruses, Plant Viruses, Bacterial, Archaeal, Fungal, Algal and Invertebrate Viruses, and Diagnosis, Treatment and Prevention of Virus Infections.

We had hoped that the new edition would 'go viral' but it was ironic that the time to publication 12 years after the previous edition had been made a bit longer due to a virus infection. The world encountered a devastating global pandemic, COVID-19, caused by a new type of a coronavirus, SARS-CoV-2. Scientists in many disciplines all over the world started immediate efforts to discover solutions as to how to mitigate and stop the spread of the pandemic. Virology moved from being a highly specialized subject to one in which everyone became a virologist, proving just how significant the different aspects of virology are in terms of understanding the nature of viral infection. Since the previous edition, the growth in the field of general virology has been enormous, including huge advances in basic science, identification of novel viruses, diagnostic methods, treatment and prevention. Taking this into account, the introduction of the articles within the Encyclopedia are very timely and crucial for providing a wealth of knowledge of the latest findings in the field of virology to a vast range of people, whether school students, undergraduates, postgraduates, teachers, scientists, researchers, journalists and others interested in infections and the conflict between the host and the pathogen.

Pandemic viruses have become a serious public concern in the changing world. We can ask ourselves whether we have reached the point in which nature can no longer cope with the consequences of increased population density and human activities that are harmful to the environment. Although several pandemics have threatened mankind before, this COVID-19 pandemic has highlighted the massive adverse economic consequences towards the wellbeing of society and the importance of research in virology.

We aimed to produce a Major Reference Work that differs in approach to others and binds all the virology disciplines together. Chapters have been included on origin, evolution and emergence of viruses, environmental virology and ecology, epidemiology, techniques for studying viruses, viral life cycles, structure, entry, genome and replication, assembly and packaging and taxonomy and viral–host interactions. Information has been included on all known species of viruses infecting bacteria, fungi, plants, vertebrates and invertebrates. Additional topics include antiviral classification and examples of their use in management of infection, diagnostic assays and vaccines, as well as the economic importance of viral diseases of crops and their control.

This edition used viral classification according to the 9th Report of the International Committee on Taxonomy of Viruses published in 2012. Updating it to the 10th Report in 2020 was affected by the pandemic and can be found online at <http://ictv.global/report/>.

We wish to acknowledge the hard work, interest, flexibility and patience, during such difficult times both socially and professionally, of everybody involved in the process of writing this edition of the Encyclopedia of Virology, especially Katarzyna Miklaszewska, Priscilla Braglia, Sam Crowe and colleagues at Elsevier. We sincerely thank all the authors and section editors for their excellent contributions to this edition.

Book Cover Image: Viruses are obligate parasites and all cells have their own viruses increasing the total number of viruses to the estimated astronomical number of 10^{31} that extends the number of stars in the universe. The viral string illustrates how pandemic viruses surround the globe. The original picture was created by Dr. Nina Atanasova (Finnish Meteorological Institute and University of Helsinki) and amended by Matthew Limbert at Elsevier.

HOW TO USE THE ENCYCLOPEDIA

Structure of the Encyclopedia

All articles in the encyclopedia are arranged thematically as a series of entries within subjects/sections, apart from volume 2 where there it was more logical to have articles arranged alphabetically.

There are three features to help you easily find the topic you are interested in: a thematic contents list, a full subject index, and contributors.

1. Thematic contents list: The alphabetical contents list, which appears at the front of each volume, lists the entries in the order that they appear in the encyclopedia.
2. Index: The index appears at the end of volume 5 and includes page numbers for quick reference to the information you are looking for. The index entries differentiate between references to a whole entry, a part of an entry, and a table or figure.
3. Contributors: At the start of each volume there is a list of the authors who contributed to all volumes.

Mustafa Adhab

University of Baghdad, Baghdad, Iraq

Alexey A. Agranovsky

Lomonosov Moscow State University, Moscow, Russia

Nasim Ahmed

*National Institute for Biotechnology and Genetic
Engineering, Faisalabad, Pakistan*

Maher Al Rwahnih

University of California, Davis, CA, United States

Olufemi J. Alabi

*Texas A&M AgriLife Research and Extension Center,
Weslaco, TX, United States*

Aurélien A. Albertini

*Institute for Integrative Biology of the Cell (I2BC),
French Alternative Energies and Atomic Energy
Commission, French National Center for Scientific
Research, Paris-Sud University, University of
Paris-Saclay, Gif-sur-Yvette, France*

Aleksandra Alimova

*The City University of New York (CUNY), School of
Medicine, The City College of New York, New York,
NY, United States*

Juan C. Alonso

*National Biotechnology Center–Spanish National
Research Council, Madrid, Spain*

Imran Amin

*National Institute for Biotechnology and Genetic
Engineering, Faisalabad, Pakistan*

Stephanie E. Ander

*University of Colorado School of Medicine, Aurora, CO,
United States*

Danielle E. Anderson

Duke-NUS Medical School, Singapore, Singapore

Ida Bagus Andika

Qingdao Agricultural University, Qingdao, China

Ana C.d.S.P. Andrade

*Federal University of Minas Gerais, Belo Horizonte,
Brazil*

Juana Angel

Pontifical Javeriana University, Bogota, Colombia

Vanesa Anton-Vazquez

King's College Hospital, London, United Kingdom

Guido Antonelli

Sapienza University of Rome, Rome, Italy

Josefa Antón

University of Alicante, Alicante, Spain

Nanako Aoki

*Tokyo University of Agriculture and Technology, Fuchu,
Japan*

Timothy D. Appleby

King's College Hospital, London, United Kingdom

Miguel Arenas

*Department of Biochemistry, Genetics and Immunology,
University of Vigo, Vigo, Spain and CINBIO
(Biomedical Research Center), University of Vigo, Vigo,
Spain*

Basil Arif

*Laboratory for Molecular Virology, Great Lakes Forestry
Centre, Sault Ste Marie, ON, Canada*

Vicente Arnau

*Institute for Integrative Systems Biology (I2SysBio),
University of Valencia–Spanish National Research
Council, Valencia, Spain*

Gaurav Arya

Duke University, Durham, NC, United States

Leyla Asadi

University of Alberta, Edmonton, AB, Canada

Sassan Asgari

The University of Queensland, Brisbane, QLD, Australia

Nina S. Atanasova

*Finnish Meteorological Institute, Helsinki, Finland and
University of Helsinki, Helsinki, Finland*

Houssam Attoui

*UMR1161 Virologie, INRAE – French National
Research Institute for Agriculture, Food and
Environment, ANSES, Ecole Nationale Vétérinaire
d'Alfort, University of Paris-Est, Maisons-Alfort, France*

Silvia Ayora

*National Biotechnology Center–Spanish National
Research Council, Madrid, Spain*

Walid Azab

Free University of Berlin, Berlin, Germany

Sasha R. Azar

*The University of Texas Medical Branch, Galveston, TX,
United States*

Fengwei Bai

*The University of Southern Mississippi, Hattiesburg, MS,
United States*

Dalan Bailey

The Pirbright Institute, Pirbright, United Kingdom

S.C. Baker

*Loyola University of Chicago, Maywood, IL,
United States*

Fausto Baldanti

*University of Pavia, Pavia, Italy and Scientific Institute
for Research, Hospitalization and Healthcare, San
Matteo Polyclinic Foundation, Pavia, Italy*

Logan Banadyga

*Public Health Agency of Canada, Winnipeg, MB,
Canada*

Ashley C. Banyard

*Animal and Plant Health Agency, Addlestone,
United Kingdom; University of West Sussex, Falmer,
United Kingdom; and St. George's Medical School,
University of London, London, United Kingdom*

Xiaoyong Bao

*The University of Texas Medical Branch, Galveston, TX,
United States*

Yiming Bao

*Beijing Institute of Genomics, Chinese Academy of
Sciences, University of Chinese Academy of Sciences,
Beijing, China*

Alan D.T. Barrett

*The University of Texas Medical Branch, Galveston, TX,
United States*

Diana P. Baquero

*Archaeal Virology Unit, Institut Pasteur, Paris, France
and Sorbonne University, Paris, France*

Moshe Bar-Joseph

*Agricultural Research Organization, Volcani Center, Bet
Dagan, Israel*

Rachael S. Barr

*Bristol Royal Hospital for Children, Bristol,
United Kingdom*

Ralf Bartenschlager

Heidelberg University, Heidelberg, Germany

David L.V. Bauer

Francis Crick Institute, London, United Kingdom

Oliver W. Bayfield

University of York, York, United Kingdom

Sally A. Baylis

Paul-Ehrlich-Institute, Langen, Germany

Philippa M. Beard

*The Pirbright Institute, Pirbright, United Kingdom and The
Roslin Institute, University of Edinburgh, United Kingdom*

Paul Becher

University of Veterinary Medicine, Hannover, Germany

Björn Becker

Saarland University, Saarbrücken, Germany

Karen L. Beemon

Johns Hopkins University, Baltimore, MD, United States

Martin Beer

Friedrich-Loeffler-Institute, Insel Riems, Germany

Jose Miguel Benito

*Health Research Institute of the Jiménez Díaz
Foundation, Autonomous University of Madrid and Rey
Juan Carlos University Hospital, Móstoles, Spain*

Mária Benkő

*Institute for Veterinary Medical Research, Center for
Agricultural Research, Budapest, Hungary*

Max Bergoin
National Institute of Scientific Research – Armand-
Frappier Health Research Centre, Laval, QC, Canada

Sabrina Bertin
Council for Agricultural Research and Economics,
Research Center for Plant Protection and Certification,
Rome, Italy

Shweta Bhatt
University of Copenhagen, Copenhagen, Denmark

Dennis K. Bideshi
California Baptist University, Riverside, CA,
United States and University of California, Riverside,
CA, United States

Yves Bigot
INRAE – French National Research Institute for
Agriculture, Food and Environment, Nouzilly, France

Richard J. Bingham
University of York, York, United Kingdom

Vera Bischoff
Institute for Chemistry and Biology of the Marine
Environment, Oldenburg, Germany

Kate N. Bishop
Francis Crick Institute, London, United Kingdom

Lindsay W. Black
The University of Maryland School of Medicine,
Baltimore, MD, United States

Romain Blanc-Mathieu
Institute for Chemical Research, Kyoto University, Kyoto,
Japan

Soile Blomqvist
National Institute for Health and Welfare, Helsinki,
Finland

Bryony C. Bonning
University of Florida, Gainesville, FL, United States

Lisa M. Bono
Rutgers, The State University of New Jersey,
New Brunswick, NJ, United States

Alexia Bordigoni
Aix-Marseille University, CNRS, IRD, Mediterranean
Institute of Oceanography, Marseille, France and
Aix-Marseille University, IRD257, Assistance-Publique
des Hôpitaux de Marseille, UMR Microbes, Evolution,
Phylogeny and Infections (MEPHI), IHU Méditerranée
Infection, Marseille, France

Mihnea Bostina
University of Otago, Dunedin, New Zealand

Maxime Boutier
University of Liège, Liège, Belgium

P.R. Bowser
Cornell University, Ithaca, NY, United States

Daniel Bradshaw
Public Health England, London, United Kingdom

Claude Bragard
University of Louvain, Louvain-la-Neuve, Belgium

Aaron C. Brault
Centers for Disease Control and Prevention, Fort Collins,
CO, United States

Nicolas Bravo-Vasquez
St. Jude Children's Research Hospital, Memphis, TN,
United States

Rob W. Briddon
University of Agriculture, Faisalabad, Pakistan

Thomas Briebe
Columbia University, New York, NY, United States

Paul Britton
The Pirbright Institute, Pirbright, United Kingdom

Thomas J. Brouwers
Athena Institute, VU Amsterdam, Amsterdam, The
Netherlands

Kevin E. Brown
Frimley Park Hospital, Frimley, United Kingdom and
Immunisation and Countermeasures Division, Public
Health England, London, United Kingdom

Corina P.D. Brussaard
NIOZ Royal Netherlands Institute for Sea Research,
Den Burg, Texel, The Netherlands and Utrecht
University, Utrecht, The Netherlands

Harald Brüssow
Laboratory of Gene Technology, Department of
Biosystems, KU Leuven, Leuven, Belgium

Joachim J. Bugert
Bundeswehr Institute of Microbiology, Munich, Germany

Jozef J. Bujarski
Northern Illinois University, DeKalb, IL, United States
and Polish Academy of Sciences, Poznan, Poland

Laura Burga
University of Otago, Dunedin, New Zealand

Sara H. Burkhard
University Hospital of Zurich, Zurich, Switzerland

Cara C. Burns
Centers for Disease Control and Prevention, Atlanta,
GA, United States

Felicity Burt
University of the Free State, Bloemfontein, South Africa

Kerry S. Burton
Leamington Spa, United Kingdom

Sarah J. Butcher
University of Helsinki, Helsinki, Finland

Mathias Büttner
Leipzig University, Leipzig, Germany

Jesse Cahill
Sandia National Labs, Albuquerque, NM, United States

Marianna Calabretto
Sapienza University of Rome, Rome, Italy

Thierry Candresse
The National Research Institute for Agriculture, Food and the Environment, University of Bordeaux, Villenave d'Ornon, France

Alan J. Cann
University of Leicester, Leicester, United Kingdom

Lorenzo Capucci
The Lombardy and Emilia Romagna Experimental Zootechnic Institute, Brescia, Italy

Irene Carlon-Andres
University of Oxford, Oxford, United Kingdom

José M. Casasnovas
National Center for Biotechnology, Spanish National Research Council (CSIC), Madrid, Spain

J.W. Casey
Cornell University, Ithaca, NY, United States

R.N. Casey
Cornell University, Ithaca, NY, United States

Sherwood R. Casjens
University of Utah, Salt Lake City, UT, United States

Antonella Casola
The University of Texas Medical Branch, Galveston, TX, United States

José R. Castón
National Center for Biotechnology, Spanish National Research Council, Madrid, Spain

Carlos E. Catalano
University of Colorado Anschutz Medical Campus, Skaggs School of Pharmacy and Pharmaceutical Sciences, Aurora, CO, United States

Roberto Cattaneo
Mayo Clinic, Rochester, MN, United States

Patrizia Cavadini
The Lombardy and Emilia Romagna Experimental Zootechnic Institute, Brescia, Italy

Supranee Chaiwatpongsakorn
Nationwide Children's Hospital, Columbus, OH, United States

Supriya Chakraborty
Jawaharlal Nehru University, New Delhi, India

Yu-Chan Chao
Institute of Molecular Biology, Academia Sinica, Taipei, Taiwan

Tyler P. Chavers
Centers for Disease Control and Prevention, Atlanta, GA, United States

Keping Chen
Jiangsu University, Zhenjiang, China

Xiaorui Chen
Genomics Research Center, Academia Sinica, Taipei, Taiwan

Yanping Chen
Bee Research Laboratory, Agricultural Research Service, US Department of Agriculture, Beltsville, MD, United States

Dayna Cheng
National Cheng Kung University, Tainan, Taiwan

Quentin Chesnais
University of Strasbourg, Colmar, France

Sotaro Chiba
Nagoya University, Nagoya, Japan

Wah Chiu
Stanford University, Stanford, CA, United States

David Chmielewski
Stanford University, Stanford, CA, United States

Irma E. Cisneros
The University of Texas Medical Branch, Galveston, TX, United States

Lark L. Coffey
University of California, Davis, CA, United States

Alanna B. Cohen
Rutgers University, New Brunswick, NJ, United States

Jeffrey I. Cohen
Laboratory of Infectious Diseases, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda, MD, United States

Seth Coleman
Rice University, Houston, TX, United States

Miquel Coll
*Institute for Research in Biomedicine, Barcelona, Spain
 and Institute for Molecular Biology of Barcelona,
 Barcelona, Spain*

John Collinge
*UCL Institute of Prion Diseases, London,
 United Kingdom*

Carina Conceicao
The Pirbright Institute, Pirbright, United Kingdom

Gabriela N. Condezo
*National Center for Biotechnology, Spanish National
 Research Council, Madrid, Spain*

Michaela J. Conley
*MRC-University of Glasgow Centre for Virus Research,
 Glasgow, United Kingdom*

Charles A Coomer
University of Oxford, Oxford, United Kingdom

Anne K. Cordes
*Hannover Medical School, Institute of Virology, Hannover,
 Germany*

Mauricio Cortes Jr.
*Department of Chemistry, College of Arts and Sciences,
 Fort Wayne, IN, United States*

Robert H.A. Coutts
University of Hertfordshire, Hatfield, United Kingdom

Jeff A. Cowley
CSIRO Livestock Industries, Brisbane, QLD, Australia

Robert W. Cross
*The University of Texas Medical Branch, Galveston, TX,
 United States*

Henryk Czosnek
The Hebrew University of Jerusalem, Rehovot, Israel

Håkon Dahle
*Department of Biological Sciences, University of Bergen,
 Bergen, Norway*

Janet M. Daly
*University of Nottingham, Sutton Bonington,
 United Kingdom*

Subha Das
Okayama University, Kurashiki, Japan

Indranil Dasgupta
University of Delhi, New Delhi, India

Sibnarayan Datta
*Defence Research Laboratory, Defence Research and
 Development Organisation (DRDO), Tezpur, Assam,
 India*

Amy Davis
*St Jude Children's Research Hospital, Memphis, TN,
 United States*

William O. Dawson
*Citrus Research and Education Center, Lake Alfred, FL,
 United States and University of Florida, Lake Alfred, FL,
 United States*

Erik De Clercq
*Rega Institute for Medical Research, KU Leuven,
 Leuven, Belgium*

Raoul J. de Groot
Utrecht University, Utrecht, The Netherlands

Juan C. de la Torre
*The Scripps Research Institute, La Jolla, CA,
 United States*

Marcelo De las Heras
University of Zaragoza, Zaragoza, Spain

Juliana Gabriela Silva de Lima
Federal University of Rio Grande do Norte, Natal, Brazil

Athos S. de Oliveira
University of Brasília, Brasília, Brazil

Nicole T. de Stefano
University of Florida, Gainesville, FL, United States

Greg Deakin
NIAB-EMR, East Malling, United Kingdom

Philippe Delfosse
University of Luxembourg, Esch-sur-Alzette, Luxembourg

Natacha Delrez
University of Liège, Liège, Belgium

Tatiana A. Demina
*Molecular and Integrative Biosciences Research Program,
 Faculty of Biological and Environmental Sciences,
 University of Helsinki, Helsinki, Finland*

Ismail Demir
*Department of Biology, Karadeniz Technical University,
 Trabzon, Turkey*

Zihni Demirbağ
*Department of Biology, Karadeniz Technical University,
 Trabzon, Turkey*

X. Deng
*Loyola University of Chicago, Maywood, IL,
 United States*

Cécile Desbiez
*Plant Pathology Unit, INRAE – French National
 Research Institute for Agriculture, Food and
 Environment, Montfavet, France*

Christelle Desnues

Aix-Marseille University, CNRS, IRD, Mediterranean Institute of Oceanography, Marseille, France and Aix-Marseille University, IRD 257, Assistance-Publique des Hôpitaux de Marseille, UMR Microbes, Evolution, Phylogeny and Infections (MEPHI), IHU Méditerranée Infection, Marseille, France

Kana Takeshita Urayama
Tokyo University of Agriculture and Technology, Fuchu, Japan

Michael E. Taliansky
The James Hutton Institute, Dundee, United Kingdom

Pan Tao
The Catholic University of America, Washington, DC, United States

Jacqueline E. Tate
Centers for Disease Control and Prevention, Atlanta, GA, United States

Satyanarayana Tatineni
Agricultural Research Service, US Department of Agriculture, Lincoln, NE, United States and University of Nebraska–Lincoln, Lincoln, NE, United States

Sisko Tauriainen
University of Turku, Turku, Finland

Norbert Tautz
University of Luebeck, Luebeck, Germany

Paulo Tavares
Institute for Integrative Biology of the Cell, CEA, CNRS, University of Paris-Sud, University of Paris-Saclay, Gif-sur-Yvette, France

Nicholas M.I. Taylor
University of Copenhagen, Copenhagen, Denmark

Xu Tengzhi
University of California, Davis, CA, United States

Raquel Tenorio
Cell Structure Laboratory, National Center for Biotechnology – Spanish National Research Council (CNB-CSIC), Madrid, Spain

Robert B. Tesh
The University of Texas Medical Branch, Galveston, TX, United States

Vaskar Thapa
Pennsylvania State University, State College, PA, United States

John E. Thomas
The University of Queensland, Brisbane, QLD, Australia

Julie A. Thomas
Rochester Institute of Technology, Rochester, NY, United States

Lynn C. Thomason
Frederick National Laboratory for Cancer Research, Frederick, MD, United States

Elizabeth Ashley Thompson
The University of Southern Mississippi, Hattiesburg, MS, United States

Jeremy R. Thompson
Cornell University, Ithaca, NY, United States

Antonio Tiberini
Council for Agricultural Research and Economics, Research Center for Plant Protection and Certification, Rome, Italy

Peter Tijssen
National Institute of Scientific Research – Armand-Frappier Health Research Centre, Microbiology and Immunology, Laval, QC, Canada

Yuji Tomaru
Japan Fisheries Research and Education Agency, Kanagawa, Japan

Laura Tomassoli
Council for Agricultural Research and Economics, Research Center for Plant Protection and Certification, Rome, Italy

Ruben Torres
National Biotechnology Center–Spanish National Research Council, Madrid, Spain

Jia Q. Truong
The University of Adelaide, Adelaide, SA, Australia

Erkki Truve[†]
Tallinn University of Technology, Tallinn, Estonia

Chih-Hsuan Tsai
Institute of Molecular Biology, Academia Sinica, Taipei, Taiwan

Roman Tuma
University of Leeds, Leeds, United Kingdom and
University of South Bohemia, České Budějovice, Czech Republic

Topi Turunen
Infectious Disease Unit, Espoo, Finland and Finnish
Institute for Health and Welfare, Helsinki, Finland

Reidun Twarock
University of York, York, United Kingdom

Ioannis E. Tzanetakis
University of Arkansas, Fayetteville, United States

Antti Vaheri
University of Helsinki, Helsinki, Finland

Eeva J. Vainio
Natural Resources Institute Finland (Luke), Helsinki, Finland

Anna M. Vaira
Institute for Sustainable Plant Protection, National
Research Council of Italy, Torino, Italy

Steven M. Valles
Center for Medical, Agricultural and Veterinary
Entomology, Agricultural Research Service, US
Department of Agriculture, Gainesville, FL,
United States

Adrián Valli
National Center for Biotechnology-Spanish National
Research Council, Madrid, Spain

Rodrigo A. Valverde
Louisiana State University Agricultural Center, Baton
Rouge, United States

Pierre Van Damme
University of Antwerp, Antwerp, Belgium

Rene A.A. van der Vlugt
Wageningen University and Research Center,
Wageningen, The Netherlands

Bernard A.M. Van der Zeijst
Leiden University Medical Center, Leiden,
The Netherlands

Koenraad Van Doorslaer
University of Arizona, Tucson, AZ, United States

James L. Van Etten
University of Nebraska–Lincoln, Lincoln, NE,
United States

Suzanne van Meer
University Medical Center Utrecht, Utrecht,
The Netherlands

Monique M. van Oers
Wageningen University and Research, Wageningen,
The Netherlands

Mark J. van Raaij
National Center for Biotechnology, Madrid, Spain

Marc H.V. Van Regenmortel
University of Strasbourg, Strasbourg, France

Piet A. van Rijn
Wageningen Bioveterinary Research, Lelystad, The
Netherlands and North-West University, Potchefstroom,
South Africa

Alain Vanderplasschen
University of Liège, Liège, Belgium

Dana L. Vanlandingham
College of Veterinary Medicine, Kansas State University,
Manhattan, KS, United States

Olli Vapalahti
Helsinki University Hospital and University of Helsinki,
Helsinki, Finland

Mark Varrelmann
Institute of Sugar Beet Research, Göttingen, Germany

Nikos Vasilakis
The University of Texas Medical Branch, Galveston, TX,
United States

Michael Veit
Free University of Berlin, Berlin, Germany

Česlovas Venclovas
Vilnius University, Vilnius, Lithuania

H. Josef Vetten
Julius Kühn Institute, Braunschweig, Germany

Marli Vlok
University of British Columbia, Vancouver, BC, Canada

Anne-Nathalie Volkoff
Diversity, Genomes and Insects-Microorganisms
Interactions, National Institute of Agricultural Research,
University of Montpellier, Montpellier, France

Ian E.H. Voorhees
Cornell University, Ithaca, NY, United States

Alex Vorsters
University of Antwerp, Antwerp, Belgium

[†]Deceased.

VOLUME 1

The Virus as a Concept – Fundamentals of Virology

A Brief History of Virology <i>David J Rowlands</i>	3
The Origin of Viruses <i>Patrick Forterre and Morgan Gaïa</i>	14
The Virocell Concept <i>Patrick Forterre</i>	23
Virus Taxonomy <i>Jens H Kuhn</i>	28
The Greater Virus World and Its Evolution <i>Eugene V Koonin and Valerian V Dolja</i>	38
The Virus Species Concept <i>Peter Simmonds</i>	47
Genetic Diversity and Evolution of Viral Populations <i>Rafael Sanjuán and Pilar Domingo-Calap</i>	53
Mechanisms of RNA Virus Evolution <i>Lisa M Bono and Siobain Duffy</i>	62
Mechanisms of DNA Virus Evolution <i>Moriah L Szpara and Koenraad Van Doorslaer</i>	71
Paleovirology <i>Clément Gilbert</i>	79
Evolution Steered by Structure <i>Nicola GA Abrescia</i>	87

Pairwise Sequence Comparison in Virology <i>Tao Zhang, Zheng Gong, Tongkun Guo, Zhuang Xiong, and Yiming Bao</i>	100
Computational Analysis of Recombination in Viral Nucleotide Sequences <i>Miguel Arenas</i>	108
Phylogeny of Viruses <i>Alexander E Gorbalenya and Chris Lauber</i>	116
Virus Bioinformatics <i>Nikolaos Pappas, Simon Roux, Martin Hölzer, Kevin Lamkiewicz, Florian Mock, Manja Marz, and Bas E Dutilh</i>	124
Metagenomics in Virology <i>Simon Roux, Jelle Matthijnsens, and Bas E Dutilh</i>	133
Database and Analytical Resources for Viral Research Community <i>Sujal Phadke, Saichetana Macherla, and Richard H Scheuermann</i>	141
Classification of the Viral World Based on Atomic Level Structures <i>Janne J Ravantti and Nicola GA Abrescia</i>	153
Isolating, Culturing, and Purifying Viruses With a Focus on Bacterial and Archaeal Viruses <i>Katri Eskelin and Hanna M Oksanen</i>	162
High Throughput Sequencing and Virology <i>Graham L Freimanis and Nick J Knowles</i>	175
Single-Virus Genomics: Studying Uncultured Viruses, One at a Time <i>Manuel Martinez-Garcia, Francisco Martinez-Hernandez, and Joaquín Martínez Martínez</i>	184
Biophysical Characterizations in the Solution State <i>Robert P Rambo and Katsuaki Inoue</i>	191
Virus Crystallography <i>Jonathan M Grimes</i>	199
Advanced Light and Correlative Microscopy in Virology <i>Sergi Padilla-Parra, Charles A Coomer, and Irene Carlon-Andres</i>	208
Atomic Force Microscopy (AFM) Investigation of Viruses <i>Alexander McPherson</i>	218
Cryo-Electron Microscopy (CEM) Structures of Viruses <i>David Chmielewski and Wah Chiu</i>	233
Analysis of Viruses in the Cellular Context by Electron Tomography <i>Peijun Zhang and Luiza Mendonça</i>	242
Mathematical Modeling of Virus Architecture <i>Reidun Twarock</i>	248
Principles of Virus Structure <i>Madhumati Sevvana, Thomas Klose, and Michael G Rossmann[†]</i>	257
Structures of Small Icosahedral Viruses <i>Elizabeth E Fry, Jingshan Ren, and Claudine Porta</i>	278
Structural Principles of the Flavivirus Particle Organization and of Its Conformational Changes <i>Stéphane Duquerroy, Arvind Sharma, and Félix A Rey</i>	290
Reoviruses (Reoviridae) and Their Structural Relatives <i>Liya Hu, Mary K Estes, and B V Venkataram Prasad</i>	303

[†]Deceased.

Structures of Tailed Phages and Herpesviruses (<i>Herpesviridae</i>) <i>Montserrat Fàbrega-Ferrer and Miquel Coll</i>	318
Adenoviruses (<i>Adenoviridae</i>) and Their Structural Relatives <i>Gabriela N Condezo, Natalia Martín-González, Marta Pérez-Illana, Mercedes Hernando-Pérez, José Gallardo, and Carmen San Martín</i>	329
Negative Single-Stranded RNA Viruses (<i>Mononegavirales</i>): A Structural View <i>Juan Reguera</i>	345
Structure of Retrovirus Particles (<i>Retroviridae</i>) <i>David K Stammers and Jingshan Ren</i>	352
Structure of Helical Viruses <i>C Martin Lawrence</i>	362
Giant Viruses and Their Virophage Parasites <i>Rodrigo AL Rodrigues, Ana CdSP Andrade, Grazielle P Oliveira, and Jônatas S Abrahão</i>	372
Viral Replication Cycle <i>AJ Cann</i>	382
Viral Receptors <i>José M Casasnovas and Thilo Stehle</i>	388
Bacterial and Archeal Virus Entry <i>Minna M Poranen and Aušra Domanska</i>	402
Nonenveloped Eukaryotic Virus Entry <i>Ian M Jones and Polly Roy</i>	409
Enveloped Virus Membrane Fusion <i>Aurélié A Albertini and Yves Gaudin</i>	417
Genome Replication of Bacterial and Archaeal Viruses <i>Česlovas Venclovas</i>	429
Viral Transcription <i>David LV Bauer and Ervin Fodor</i>	439
Translation of Viral Proteins <i>Martin D Ryan and Garry A Luke</i>	444
Recombination <i>Jozef J Bujarski</i>	460
Assembly of Viruses: Enveloped Particles <i>CK Navaratnarajah, R Warriar, and RJ Kuhn</i>	468
Assembly of Viruses: Nonenveloped Particles <i>M Luo</i>	475
Virion Assembly: From Small Picornaviruses (<i>Picornaviridae</i>) to Large Herpesviruses (<i>Herpesviridae</i>) <i>Ling Zhu, Nan Wang, and Xiangxi Wang</i>	480
Genome Packaging <i>Richard J Bingham, Reidun Twarock, Carlos P Mata, and Peter G Stockley</i>	488
Virus Factories <i>Isabel Fernández de Castro, Raquel Tenorio, and Cristina Risco</i>	495
Release of Phages From Prokaryotic Cells <i>Jesse Cahill and Ry Young</i>	501
Virus Budding <i>Lara Rheinemann and Wesley I Sundquist</i>	519

Vesicle-Mediated Transcytosis and Export of Viruses <i>Efraín E Rivera-Serrano and Stanley M Lemon</i>	529
Vector Transmission of Animal Viruses <i>Houssam Attoui, Fauziah Mohd Jaafar, Rennos Fragkoudis, and Peter PC Mertens</i>	542
The Human Virome <i>Alexia Bordigoni, Sébastien Halary, and Christelle Desnues</i>	552
Epidemiology of Human and Animal Viral Diseases <i>Michael Edelstein</i>	559
Zoonosis, Emerging and Re-Emerging Viral Diseases <i>Janet M Daly</i>	569
Antiviral Innate Immunity: Introduction <i>Friedemann Weber</i>	577
Humoral and T Cell-Mediated Immunity to Viruses <i>Ane Ogbe and Lucy Dorrell</i>	584
Antigenicity and Antigenic Variation <i>Kuan-Ying A Huang, Xiaorui Chen, Che Ma, Dayna Cheng, Jen-Ren Wang, and Wan-Chun Lai</i>	597
Antigen Presentation <i>Andrew J McMichael</i>	601
Defense Against Viruses and Other Genetic Parasites in Prokaryotes <i>Kira S Makarova, Yuri I Wolf, and Eugene V Koonin</i>	606
Defective-Interfering Viruses <i>L Roux</i>	617
Ecology and Global Impacts of Viruses <i>Joanne B Emerson</i>	621
The Role of Retroviruses in Cellular Evolution <i>Andrea Kirmaier and Welkin E Johnson</i>	627
The Role of Bacteriophages in Bacterial Evolution <i>Chris M Rands and Harald Brüssow</i>	633
Viruses and Their Potential for Bioterrorism <i>Dana L Vanlandingham and Stephen Higgs</i>	644
The Use of Viral Promoters in Expression Vectors <i>Ian M Jones</i>	652
Oncolytic Viruses <i>Laura Burga and Mihnea Bostina</i>	658
Biotechnology Approaches to Modern Vaccine Design <i>George P Lomonosoff and Daniel Ponndorf</i>	662
Viruses: Impact on Science and Society <i>Neeraja Sankaran and Robin A Weiss</i>	671

VOLUME 2

Viruses as Infectious Agents: Human and Animal Viruses

Adenoviruses (<i>Adenoviridae</i>) <i>Balázs Harrach and Mária Benkő</i>	3
---	---

African Horse Sickness Virus (<i>Reoviridae</i>) <i>Piet A van Rijn</i>	17
African Swine Fever Virus (<i>Asfarviridae</i>) <i>Linda K Dixon, Rachel Nash, Philippa C Hawes, and Christopher L Netherton</i>	22
Akabane Virus and Schmallenberg Virus (<i>Peribunyaviridae</i>) <i>Martin Beer and Kerstin Wernike</i>	34
Alphaviruses Causing Encephalitis (<i>Togaviridae</i>) <i>Diane E Griffin</i>	40
Anelloviruses (<i>Anelloviridae</i>) <i>Fabrizio Maggi and Mauro Pistello</i>	48
Animal Lentiviruses (<i>Retroviridae</i>) <i>Esperanza Gomez-Lucia</i>	56
Animal Morbilliviruses (<i>Paramyxoviridae</i>) <i>Carina Conceicao and Dalan Bailey</i>	68
Animal Papillomaviruses (<i>Papillomaviridae</i>) <i>John S Munday</i>	79
Astroviruses (<i>Astroviridae</i>) <i>Virginia Hargest, Amy Davis, and Stacey Schultz-Cherry</i>	92
Avian Hepadnaviruses (<i>Hepadnaviridae</i>) <i>Allison R Jilbert, Georget Y Reaiche-Miller, and Catherine A Scougall</i>	100
Avian Herpesviruses (<i>Herpesviridae</i>) <i>Vishwanatha RAP Reddy and Venugopal Nair</i>	112
Avian Influenza Viruses (<i>Orthomyxoviridae</i>) <i>Nicolas Bravo-Vasquez and Stacey Schultz-Cherry</i>	117
Avian Leukosis and Sarcoma Viruses (<i>Retroviridae</i>) <i>Karen L Beemon</i>	122
Bluetongue Virus (<i>Reoviridae</i>) <i>Raghavendran Kulasegaran-Shylini and Polly Roy</i>	127
Borna Disease Virus and Related Bornaviruses (<i>Bornaviridae</i>) <i>Susan L Payne</i>	137
Bovine Leukemia Virus (<i>Retroviridae</i>) <i>Thomas Joris, Roghaiyeh Safari, Jean-Rock Jacques, and Luc Willems</i>	144
Bovine Viral Diarrhea, Border Disease, and Classical Swine Fever Viruses (<i>Flaviviridae</i>) <i>Paul Becher, Volker Moennig, and Norbert Tautz</i>	153
Capripoxviruses, Parapoxviruses, and Other Poxviruses of Ruminants (<i>Poxviridae</i>) <i>Philippa M Beard</i>	165
Chikungunya Virus (<i>Togaviridae</i>) <i>Thomas E Morrison and Stephanie E Ander</i>	173
Circoviruses (<i>Circoviridae</i>) <i>Giovanni Franzo and Joaquim Segalés</i>	182
Coronaviruses: General Features (<i>Coronaviridae</i>) <i>Paul Britton</i>	193
Coronaviruses: Molecular Biology (<i>Coronaviridae</i>) <i>X Deng and SC Baker</i>	198

Crimean-Congo Hemorrhagic Fever Virus and Nairoviruses of Medical Importance (<i>Nairoviridae</i>) <i>Ali Mirazimi, Felicity Burt, and Anna Papa</i>	208
Dengue Viruses (<i>Flaviviridae</i>) <i>Ashley L. St. John and Duane J. Gubler</i>	218
Ebola Virus (<i>Filoviridae</i>) <i>Andrea Marzi and Logan Banadyga</i>	232
Enteroviruses (<i>Picornaviridae</i>) <i>Carita Savolainen-Kopra, Soile Blomqvist, and Petri Susi</i>	245
Enveloped, Positive-Strand RNA Viruses (<i>Nidovirales</i>) <i>L. Enjuanes, AE Gorbalenya, RJ de Groot, JA Cowley, J Ziebuhr, and EJ Snijder</i>	256
Epstein-Barr Virus (<i>Herpesviridae</i>) <i>Lawrence S. Young</i>	267
Equine Herpesviruses (<i>Herpesviridae</i>) <i>Gisela Soboll-Hussey, Nikolaus Osterrieder, and Walid Azab</i>	278
Equine, Canine, and Swine Influenza (<i>Orthomyxoviridae</i>) <i>Janet M. Daly and Japhette E. Kembou-Ringert</i>	287
Feline Calicivirus (<i>Caliciviridae</i>) <i>Margaret J. Hosie and Michaela J. Conley</i>	294
Feline Leukemia and Sarcoma Viruses (<i>Retroviridae</i>) <i>Brian J. Willett and Margaret J. Hosie</i>	300
Fish and Amphibian Alloherpesviruses (<i>Herpesviridae</i>) <i>Maxime Boutier, Léa Morvan, Natacha Delrez, Francesco Origi, Andor Doszpoly, and Alain Vanderplasschen</i>	306
Fish Retroviruses (<i>Retroviridae</i>) <i>TA Paul, RN Casey, PR Bowser, JW Casey, J Rovnak, and SL Quackenbush</i>	316
Fish Rhabdoviruses (<i>Rhabdoviridae</i>) <i>Gael Kurath and David Stone</i>	324
Foot-and-Mouth Disease Viruses (<i>Picornaviridae</i>) <i>David J. Rowlands</i>	332
Fowlpox Virus and Other Avipoxviruses (<i>Poxviridae</i>) <i>Efstathios S. Giotis and Michael A. Skinner</i>	343
Hantaviruses (<i>Hantaviridae</i>) <i>Tarja Sironen and Antti Vaheri</i>	349
Henipaviruses (<i>Paramyxoviridae</i>) <i>Lin-Fa Wang and Danielle E. Anderson</i>	355
Hepatitis A Virus (<i>Picornaviridae</i>) <i>Andreas Dotzauer</i>	362
Hepatitis B Virus (<i>Hepadnaviridae</i>) <i>Peter Karayiannis</i>	373
Hepatitis C Virus (<i>Flaviviridae</i>) <i>Ralf Bartenschlager and Keisuke Tabata</i>	386
Hepeviruses (<i>Hepeviridae</i>) <i>Xiang-Jin Meng</i>	397
Herpes Simplex Virus 1 and 2 (<i>Herpesviridae</i>) <i>David M. Knipe and Richard Whitley</i>	404

History of Virology: Vertebrate Viruses <i>F Fenner</i>	414
Human Boca- and Protoparvoviruses (<i>Parvoviridae</i>) <i>Maria Söderlund-Venermo and Jianming Qiu</i>	419
Human Coronavirus-229E, -OC43, -NL63, and -HKU1 (<i>Coronaviridae</i>) <i>Ding X Liu, Jia Q Liang, and To S Fung</i>	428
Human Cytomegalovirus (<i>Herpesviridae</i>) <i>Edward S Mocarski</i>	441
Human Immunodeficiency Virus (<i>Retroviridae</i>) <i>Blaide Woodburn, Ann Emery, and Ronald Swanstrom</i>	460
Human Metapneumovirus (<i>Pneumoviridae</i>) <i>Antonella Casola, Matteo P Garofalo, and Xiaoyong Bao</i>	475
Human Norovirus and Sapovirus (<i>Caliciviridae</i>) <i>Sumit Sharma, Marie Hagbom, Lennart Svensson, and Johan Nordgren</i>	483
Human Papillomaviruses (<i>Papillomaviridae</i>) <i>Alison A McBride and Samuel S Porter</i>	493
Human Parainfluenza Viruses (<i>Paramyxoviridae</i>) <i>Elisabeth Adderson</i>	502
Human Pathogenic Arenaviruses (<i>Arenaviridae</i>) <i>Sheli R Radoshitzky and Juan C de la Torre</i>	507
Human Polyomaviruses (<i>Papillomaviridae</i>) <i>Melissa S Maginnis</i>	518
Human T-Cell Leukemia Virus-1 and -2 (<i>Retroviridae</i>) <i>Amanda R Panfil and Patrick L Green</i>	528
Infectious Bursal Disease Virus (<i>Birnaviridae</i>) <i>Daral J Jackwood</i>	540
Infectious Pancreatic Necrosis Virus (<i>Birnaviridae</i>) <i>Øystein Evensen</i>	544
Influenza A Viruses (<i>Orthomyxoviridae</i>) <i>Laura Kakkola, Niina Ikonen, and Ilkka Julkunen</i>	551
Influenza B, C and D Viruses (<i>Orthomyxoviridae</i>) <i>Thorsten Wolff and Michael Veit</i>	561
Jaagsiekte Sheep Retrovirus (<i>Retroviridae</i>) <i>James M Sharp, Marcelo De las Heras, Massimo Palmarini, and Thomas E Spencer</i>	575
Japanese Encephalitis Virus (<i>Flaviviridae</i>) <i>Sang-Im Yun and Young-Min Lee</i>	583
Kaposi's Sarcoma-Associated Herpesvirus (<i>Herpesviridae</i>) <i>Anne K Cordes and Thomas F Schulz</i>	598
Marburg and Ravn Viruses (<i>Filoviridae</i>) <i>Courtney Woolsey, Thomas W Geisbert, and Robert W Cross</i>	608
Measles Virus (<i>Paramyxoviridae</i>) <i>Roberto Cattaneo and Michael McChesney</i>	619
Molluscum Contagiosum Virus (<i>Poxviridae</i>) <i>Joachim J Bugert and Rosina Ehmann</i>	629

Mumps Virus (<i>Paramyxoviridae</i>) <i>Stephen A Winchester and Kevin E Brown</i>	634
Murine Leukemia and Sarcoma Viruses (<i>Retroviridae</i>) <i>George R Young and Kate N Bishop</i>	643
Newcastle Disease Virus (<i>Paramyxoviridae</i>) <i>Ben Peeters and Guus Koch</i>	648
Orthobunyaviruses (<i>Peribunyaviridae</i>) <i>Alyssa B Evans, Clayton W Winkler, and Karin E Peterson</i>	654
Parapoxviruses (<i>Poxviridae</i>) <i>Hanns-Joachim Rziha and Mathias Büttner</i>	666
Parechoviruses (<i>Picornaviridae</i>) <i>Sisko Tauriainen and Glyn Stanway</i>	675
Parvoviruses of Carnivores, and the Emergence of Canine Parvovirus (<i>Parvoviridae</i>) <i>Colin R Parrish, Ian EH Voorhees, and Susan L Hafenstein</i>	683
Polioviruses (<i>Picornaviridae</i>) <i>Philip D Minor</i>	688
Porcine Reproductive and Respiratory Syndrome Virus and Equine Arteritis Virus (<i>Arteriviridae</i>) <i>Jianqiang Zhang, Alan T Loynachan, Gregory W Stevenson, and Jeffrey J Zimmerman</i>	697
Prions of Vertebrates <i>Jonathan DF Wadsworth and John Collinge</i>	707
Pseudorabies Virus (<i>Herpesviridae</i>) <i>Thomas C Mettenleiter and Barbara G Klupp</i>	714
Rabbit Hemorrhagic Disease Virus and European Brown Hare Syndrome Virus (<i>Caliciviridae</i>) <i>Lorenzo Capucci, Patrizia Cavadini, and Antonio Lavazza</i>	724
Rabbit Myxoma Virus and the Fibroma Viruses (<i>Poxviridae</i>) <i>Peter J Kerr</i>	730
Rabies and Other Lyssaviruses (<i>Rhabdoviridae</i>) <i>Ashley C Banyard and Anthony R Fooks</i>	738
Respiratory Syncytial Virus (<i>Pneumoviridae</i>) <i>Tiffany King, Tiffany Jenkins, Supranee Chaiwatpongsakorn, and Mark E Peebles</i>	747
Rhinoviruses (<i>Picornaviridae</i>) <i>Matti Waris and Olli Ruuskanen</i>	757
Rift Valley Fever Virus and Other Phleboviruses (<i>Phenuiviridae</i>) <i>Tetsuro Ikegami</i>	765
Roseoloviruses: Human Herpesviruses 6A, 6B and 7 (<i>Herpesviridae</i>) <i>Katherine N Ward</i>	778
Rotaviruses (<i>Reoviridae</i>) <i>Juana Angel and Manuel A Franco</i>	789
Rubella Virus (<i>Picornaviridae</i>) <i>Annette Mankertz</i>	797
Saint Louis Encephalitis Virus (<i>Flaviviridae</i>) <i>William K Reisen, Lark L Coffey, Daniele M Swetnam, and Aaron C Brault</i>	805
Severe Acute Respiratory Syndrome (SARS) and Middle East Respiratory Syndrome (MERS) (<i>Coronaviridae</i>) <i>Joseph SM Peiris and Leo LM Poon</i>	814

Severe Acute Respiratory Syndrome Coronavirus 2 (SARS-CoV-2) (<i>Coronaviridae</i>) <i>Malik Peiris</i>	825
Simian Immunodeficiency Virus (SIV) and HIV-2 (<i>Retroviridae</i>) <i>Phyllis J Kanki</i>	827
Sindbis Virus (<i>Togaviridae</i>) <i>Satu Kurkela</i>	837
Tick-Borne Encephalitis Virus (<i>Flaviviridae</i>) <i>Teemu Smura, Suvi Kuivanen, and Olli Vapalahti</i>	843
Transmissible Gastroenteritis Virus of Pigs and Porcine Epidemic Diarrhea Virus (<i>Coronaviridae</i>) <i>Qiang Liu and Volker Gerds</i>	850
Vaccinia Virus (<i>Poxviridae</i>) <i>Yan Xiang and Rebecca K Lane</i>	854
Varicella-Zoster Virus (<i>Herpesviridae</i>) <i>Jeffrey I Cohen</i>	860
Variola and Monkeypox Viruses (<i>Poxviridae</i>) <i>Lalita Priyamvada and Panayampalli S Satheshkumar</i>	868
Vesicular Stomatitis Virus and Bovine Ephemeral Fever Virus (<i>Rhabdoviridae</i>) <i>Peter J Walker and Robert B Tesh</i>	875
West Nile Virus (<i>Flaviviridae</i>) <i>Fengwei Bai and Elizabeth Ashley Thompson</i>	884
Yellow Fever Virus (<i>Flaviviridae</i>) <i>Ashley E Strother and Alan DT Barrett</i>	891
Zika Virus (<i>Flaviviridae</i>) <i>Nikos Vasilakis, Shannan L Rossi, Sasha R Azar, Irma E Cisneros, Cassia F Estofolete, and Mauricio L Nogueira</i>	899

VOLUME 3

Viruses as Infectious Agents: Plant Viruses

An Introduction to Plant Viruses <i>Roger Hull</i>	3
Emerging and Re-Emerging Plant Viruses <i>Sabrina Bertin, Francesco Faggioli, Andrea Gentili, Ariana Manglli, Anna Taglienti, Antonio Tiberini, and Laura Tomassoli</i>	8
Emerging Geminiviruses (<i>Geminiviridae</i>) <i>Muhammad S Nawaz-ul-Rehman, Nazia Nahid, and Muhammad Mubin</i>	21
Movement of Viruses in Plants <i>Manfred Heinlein</i>	32
Plant Antiviral Defense: Gene-Silencing Pathways <i>Vitantonio Pantaleo, Chikara Masuta, and Hanako Shimura</i>	43
Plant Resistance to Viruses: Engineered Resistance <i>Marc Fuchs</i>	52
Plant Resistance to Viruses: Natural Resistance Associated With Dominant Genes <i>Mandy Ravensbergen and Richard Kormelink</i>	60

Plant Resistance to Viruses: Natural Resistance Associated With Recessive Genes <i>Masayoshi Hashimoto, Kensaku Maejima, Yasuyuki Yamaji, and Shigetou Namba</i>	69
Plant Viral Diseases: Economic Implications <i>Basavaprabhu L Patil</i>	81
Retrotransposons of Plants <i>M-A Grandbastien</i>	98
Vector Transmission of Plant Viruses <i>Etienne Herrbach and Quentin Chesnais</i>	106
Viral Suppressors of Gene Silencing <i>Hernan Garcia-Ruiz</i>	116
Virus-Induced Gene Silencing (VIGS) <i>Xu Tengzhi, Ugrappa Nagalakshmi, and Savithramma P Dinesh-Kumar</i>	123
Alfalfa Mosaic Virus (<i>Bromoviridae</i>) <i>L Sue Loesch-Fries</i>	132
Alphaflexiviruses (<i>Alphaflexiviridae</i>) <i>Sergey Y Morozov and Alexey A Agranovsky</i>	140
Alphasatellites (<i>Alphasatellitidae</i>) <i>Rob W Briddon and Muhammad S Nawaz-ul-Rehman</i>	149
Amalgaviruses (<i>Amalgaviridae</i>) <i>Ioannis E Tzanetakis, Sead Sabanadzovic, and Rodrigo A Valverde</i>	154
Badnaviruses (<i>Caulimoviridae</i>) <i>Andrew DW Geering</i>	158
Banana Bunchy Top Virus (<i>Nanoviridae</i>) <i>John E Thomas</i>	169
Barley Yellow Dwarf Viruses (<i>Luteoviridae</i>) <i>Leslie L Domier</i>	176
Bean Common Mosaic Virus and Bean Common Mosaic Necrosis Virus (<i>Potyviridae</i>) <i>Ramon Jordan and John Hammond</i>	184
Bean Golden Mosaic Virus and Bean Golden Yellow Mosaic Virus (<i>Geminiviridae</i>) <i>Francisco M Zerbini and Simone G Ribeiro</i>	192
Beet Curly Top Virus (<i>Geminiviridae</i>) <i>Robert L Gilbertson, Tomas A Melgarejo, Maria R Rojas, William M Wintermantel, and John Stanley</i>	200
Beet Necrotic Yellow Vein Virus (<i>Benyviridae</i>) <i>Sebastian Liebe, Annette Niehl, Renate Koenig, and Mark Varrelmann</i>	213
Benyviruses (<i>Benyviridae</i>) <i>Annette Niehl, Sebastian Liebe, Mark Varrelmann, and Renate Koenig</i>	219
Betaflexiviruses (<i>Betaflexiviridae</i>) <i>Nobuyuki Yoshikawa and Hajime Yaegashi</i>	229
Betasatellites and Deltasatellites (<i>Toleusatellitidae</i>) <i>Muhammad S Nawaz-ul-Rehman, Nazia Nahid, Muhammad Hassan, and Muhammad Mubin</i>	239
Bluner-, Cile-, and Higreviruses (<i>Kitaviridae</i>) <i>Diego F Quito-Avila, Juliana Freitas-Astúa, and Michael J Melzer</i>	247
Brome Mosaic Virus (<i>Bromoviridae</i>) <i>Guijuan He, Zhenlu Zhang, Preethi Sathanantham, Arturo Diaz, and Xiaofeng Wang</i>	252

Bromoviruses (<i>Bromoviridae</i>) <i>Jozef J Bujarski</i>	260
Bymoviruses (<i>Potyviridae</i>) <i>Annette Niehl and Frank Rabenstein</i>	268
Cacao Swollen Shoot Virus (<i>Caulimoviridae</i>) <i>Emmanuelle Muller</i>	274
Carmo-Like Viruses (<i>Tombusviridae</i>) <i>Miryam Pérez-Cañamás and Carmen Hernández</i>	285
Cassava Brown Streak Viruses (<i>Potyviridae</i>) <i>Basavaprabhu L Patil</i>	293
Cassava Mosaic Viruses (<i>Geminiviridae</i>) <i>James Legg and Stephan Winter</i>	301
Caulimoviruses (<i>Caulimoviridae</i>) <i>James E Schoelz and Mustafa Adhab</i>	313
Cheraviruses, Sadwaviruses and Torradoviruses (<i>Secoviridae</i>) <i>Toru Iwanami and René AA van der Vlugt</i>	322
Citrus Tristeza Virus (<i>Closteroviridae</i>) <i>Moshe Bar-Joseph, Scott J Harper, and William O Dawson</i>	327
Closteroviruses (<i>Closteroviridae</i>) <i>Marc Fuchs</i>	336
Comoviruses and Fabaviruses (<i>Secoviridae</i>) <i>George P Lomonossoff</i>	348
Cotton Leaf Curl Disease (<i>Geminiviridae</i>) <i>Nasim Ahmed, Imran Amin, and Shahid Mansoor</i>	355
Cowpea Mosaic Virus (<i>Secoviridae</i>) <i>George P Lomonossoff</i>	364
Cucumber Mosaic Virus (<i>Bromoviridae</i>) <i>Judith Hirsch and Benoît Moury</i>	371
Dianthovirus (<i>Tombusviridae</i>) <i>Kiwamu Hyodo and Masanori Kaido</i>	383
Endornaviruses (<i>Endornaviridae</i>) <i>Toshiyuki Fukuhara</i>	388
Fimoviruses (<i>Fimoviridae</i>) <i>Toufic Elbeaino and Michele Digiaro</i>	396
Furoviruses (<i>Virgaviridae</i>) <i>Annette Niehl and Renate Koenig</i>	405
Geminiviruses (<i>Geminiviridae</i>) <i>Jesús Navas-Castillo and Elvira Fiallo-Olivé</i>	411
Hordeiviruses (<i>Virgaviridae</i>) <i>Zhihao Jiang, Meng Yang, Yongliang Zhang, Andrew O Jackson, and Dawei Li</i>	420
Idaeoviruses (<i>Mayoviridae</i>) <i>Robert R Martin and Karen E Keller</i>	430
Ilarviruses (<i>Bromoviridae</i>) <i>Aaron Simkovich, Susanne E Kohalmi, and Aiming Wang</i>	439

Luteoviruses (<i>Luteoviridae</i>) <i>Leslie L Domier</i>	447
Machlomovirus and Panicoviruses (<i>Tombusviridae</i>) <i>Kay Scheets</i>	456
Maize Streak Virus (<i>Geminiviridae</i>) <i>Darren P Martin and Aderito L Monjane</i>	461
Nanoviruses (<i>Nanoviridae</i>) <i>Bruno Gronenborn and H Josef Vetten</i>	470
Necro-Like Viruses (<i>Tombusviridae</i>) <i>Luisa Rubino and Giovanni P Martelli[†]</i>	481
Nepoviruses (<i>Secoviridae</i>) <i>Hélène Sanfaçon</i>	486
Ophioviruses (<i>Aspiviridae</i>) <i>Anna M Vaira and John Hammond</i>	495
Orthospoviruses (<i>Tospoviridae</i>) <i>Renato O Resende and Hanu R Pappu</i>	507
Ourmiaviruses (<i>Botourmiaviridae</i>) <i>Gian Paolo Accotto and Cristina Rosa</i>	516
Papaya Ringspot Virus (<i>Potyviridae</i>) <i>Cécile Desbiez and Hervé Lecoq</i>	520
Pecluviruses (<i>Virgaviridae</i>) <i>Hema Masarapu, Pothur Sreenivasulu, Philippe Delfosse, Claude Bragard, Anne Legreve, and DVR Reddy</i>	528
Pepino Mosaic Virus (<i>Alphaflexiviridae</i>) <i>Rene AA van der Vlugt and CCMM Stijger</i>	539
Plant Reoviruses (<i>Reoviridae</i>) <i>Yu Huang and Yi Li</i>	545
Plant Resistance to Geminiviruses <i>Basavaprabhu L Patil, Supriya Chakraborty, Henryk Czosnek, Elvira Fiallo-Olivé, Robert L Gilbertson, James Legg, Shahid Mansoor, Jesús Navas-Castillo, Rubab Z Naqvi, Saleem U Rahman, and Francisco M Zerbini</i>	554
Plant Rhabdoviruses (<i>Rhabdoviridae</i>) <i>Ralf G Dietzgen, Michael M Goodin, and Zhenghe Li</i>	567
Plant Satellite Viruses (<i>Albetovirus, Aumaivirus, Papanivirus, Virtovirus</i>) <i>Mart Krupovic</i>	581
Plum Pox Virus (<i>Potyviridae</i>) <i>Miroslav Glasa and Thierry Candresse</i>	586
Poleroviruses (<i>Luteoviridae</i>) <i>Hernan Garcia-Ruiz, Natalie M Holste, and Katherine LaTourrette</i>	594
Pomoviruses (<i>Virgaviridae</i>) <i>Eugene I Savenkov</i>	603
Potato Virus Y (<i>Potyviridae</i>) <i>Laurent Glais and Benoît Moury</i>	612
Potexviruses (<i>Alphaflexiviridae</i>) <i>Ki H Ryu, Eun G Song, and Jin S Hong</i>	623

[†]Deceased.

Potyviruses (<i>Potyviridae</i>) <i>Adrián Valli, Juan A García, and Juan J López-Moya</i>	631
Quinviruses (<i>Betaflexiviridae</i>) <i>Ki H Ryu and Eun G Song</i>	642
Reverse-Transcribing Viruses (<i>Belpaoviridae, Metaviridae, and Pseudoviridae</i>) <i>Carlos Llorens, Beatriz Soriano, Maria A Navarrete-Muñoz, Ahmed Hafez, Vicente Arnau, Jose Miguel Benito, Toni Gabaldon, Norma Rallon, Jaume Pérez-Sánchez, and Mart Krupovic</i>	653
Rice Tungro Disease (<i>Secoviridae, Caulimoviridae</i>) <i>Gaurav Kumar, Fauzia Zarreen, and Indranil Dasgupta</i>	667
Rice Yellow Mottle Virus (<i>Solemoviridae</i>) <i>Eugénie Hébrard, Nils Poulicard, and Mbolarinosy Rakotomalala</i>	675
Satellite Nucleic Acids and Viruses <i>Olufemi J Alabi, Alfredo Diaz-Lara, and Maher Al Rwahnih</i>	681
Secoviruses (<i>Secoviridae</i>) <i>Jeremy R Thompson</i>	692
Sequiviruses and Waikaviruses (<i>Secoviridae</i>) <i>Lucy Rae Stewart</i>	703
Solemoviruses (<i>Solemoviridae</i>) <i>Cecilia Sarmiento, Merike Sõmera, and Erkki Truve[†]</i>	712
Tenuiviruses (<i>Phenuiviridae</i>) <i>Bertha Cecilia Ramirez and Anne-Lise Haenni</i>	719
Tobacco Mosaic Virus (<i>Virgaviridae</i>) <i>Marc HV Van Regenmortel</i>	727
Tobamoviruses (<i>Virgaviridae</i>) <i>Ulrich Melcher, Dennis J Lewandowski, and William O Dawson</i>	734
Tobraviruses (<i>Virgaviridae</i>) <i>Stuart A MacFarlane</i>	743
Tomato Leaf Curl New Delhi Virus (<i>Geminiviridae</i>) <i>Supriya Chakraborty and Manish Kumar</i>	749
Tomato Spotted Wilt Virus (<i>Tospoviridae</i>) <i>Hanu R Pappu, Anna E Whitfield, and Athos S de Oliveira</i>	761
Tomato Yellow Leaf Curl Viruses (<i>Geminiviridae</i>) <i>Henryk Czosnek</i>	768
Tombusvirus-Like Viruses (<i>Tombusviridae</i>) <i>K Andrew White</i>	778
Tombusviruses (<i>Tombusviridae</i>) <i>Luisa Rubino and Kay Scheets</i>	788
Tritimoviruses and Rymoviruses (<i>Potyviridae</i>) <i>Satyanarayana Tatineni and Gary L Hein</i>	797
Triviruses (<i>Betaflexiviridae</i>) <i>Yahya ZA Gaafar and Heiko Ziebell</i>	805
Tymoviruses (<i>Tymoviridae</i>) <i>Rosemarie W Hammond and Peter Abrahamian</i>	818

[†]Deceased.

Umbraviruses (<i>Tombusviridae</i>) <i>Eugene V Ryabov and Michael E Taliansky</i>	827
Varicosaviruses (<i>Rhabdoviridae</i>) <i>Takahide Sasaya</i>	833
Virgaviruses (<i>Virgaviridae</i>) <i>Eugene I Savenkov</i>	839
Viroids (<i>Pospiviroidae</i> and <i>Avsunviroidae</i>) <i>Ricardo Flores and Robert A Owens</i>	852
Watermelon Mosaic Virus and Zucchini Yellow Mosaic Virus (<i>Potyviridae</i>) <i>Cécile Desbiez and Hervé Lecoq</i>	862

Viruses as Infectious Agents: Bacterial, Archaeal, Fungal, Algal, and Invertebrate Viruses

Bacterial Viruses

History of Virology: Bacteriophages <i>William C Summers</i>	3
Icosahedral Phages – Single-Stranded DNA (ϕ X174) <i>Bentley A Fane and Aaron P Roznowski</i>	10
Single-Stranded RNA Bacterial Viruses <i>Peter G Stockley and Junjie Zhang</i>	21
Enveloped Icosahedral Phages – Double-Stranded RNA (ϕ 6) <i>Paul Gottlieb and Aleksandra Alimova</i>	26
Membrane-Containing Icosahedral DNA Bacteriophages <i>Roman Tuma, Sarah J Butcher, and Hanna M Oksanen</i>	36
Tailed Double-Stranded DNA Phages <i>Robert L Duda</i>	45
Helical and Filamentous Phages <i>Andreas Kuhn and Sebastian Leptihn</i>	53
Replication of <i>Bacillus</i> Double-Stranded DNA Bacteriophages <i>Silvia Ayora, Paulo Tavares, Ruben Torres, and Juan C Alonso</i>	61
Lytic Transcription <i>William McAllister and Deborah M Hinton</i>	69
Lysogeny <i>Keith E Shearwin and Jia Q Truong</i>	77
Decision Making by Temperate Phages <i>Ido Golding, Seth Coleman, Thu VP Nguyen, and Tianyou Yao</i>	88
Mobilization of Phage Satellites <i>Kristen N LeGault and Kimberley D Seed</i>	98
Portal Vertex <i>Peng Jing and Mauricio Cortes Jr.</i>	105

Prohead, the Head Shell Pre-Cursor <i>Marc C Morais and Michael E Woodson</i>	115
Enzymology of Viral DNA Packaging Machines <i>Carlos E Catalano</i>	124
DNA Packaging: DNA Recognition <i>Sandra J Greive and Oliver W Bayfield</i>	136
DNA Packaging: The Translocation Motor <i>Janelle A Hayes and Brian A Kelch</i>	148
Biophysics of DNA Packaging <i>Joshua Pajak, Gaurav Arya, and Douglas E Smith</i>	160
Energetics of the DNA-Filled Head <i>Alex Evilevitch</i>	167
Bacteriophage Receptor Proteins of Gram-Negative Bacteria <i>Sarah M Doore, Kristin N Parent, Sundharraman Subramanian, Jason R Schrad, and Natalia B Hubbs</i>	175
Tail Structure and Dynamics <i>Shweta Bhatt, Petr G Leiman, and Nicholas MI Taylor</i>	186
Bacteriophage Tail Fibres, Tailspikes, and Bacterial Receptor Interaction <i>Mateo Seoane-Blanco, Mark J van Raaij, and Meritxell Granell</i>	194
Phage Genome and Protein Ejection In Vivo <i>Ian J Molineux, L Letti Lopez, and Aaron P Roznowski</i>	206
Dealing With the Whole Head: Diversity and Function of Capsid Ejection Proteins in Tailed Phages <i>Lindsay W Black and Julie A Thomas</i>	219
Jumbo Phages <i>Isaac T Younker and Carol Duffy</i>	229
CRISPR-Cas Systems and Anti-CRISPR Proteins: Adaptive Defense and Counter-Defense in Prokaryotes and Their Viruses <i>Asma Hatoum-Aslan and Olivia G Howell</i>	242
Bacteriophage: Therapeutics and Diagnostics Development <i>Teng-Chieh Yang</i>	252
Bacteriophage Vaccines <i>Pan Tao and Venigalla B Rao</i>	259
Bacteriophage Diversity <i>Julianne H Grose and Sherwood R Casjens</i>	265
Genetic Mosaicism in the Tailed Double-Stranded DNA Phages <i>Welkin H Pope</i>	276
Bacteriophages of the Human Microbiome <i>Pilar Manrique, Michael Dills, and Mark J Young</i>	283
Bacteriophage: Red Recombination System and the Development of Recombineering Technologies <i>Lynn C Thomason and Kenan C Murphy</i>	291
Nanotechnology Application of Bacteriophage DNA Packaging Nanomotors <i>Tao Weitao, Lixia Zhou, Zhefeng Li, Long Zhang, and Peixuan Guo</i>	302
General Ecology of Bacteriophages <i>Stephen T Abedon</i>	314
Marine Bacteriophages <i>Vera Bischoff, Falk Zucker, and Cristina Moraru</i>	322

Ecology of Phages in Extreme Environments <i>Tatiana A Demina and Nina S Atanasova</i>	342
---	-----

Archaeal Viruses

Diversity of Hyperthermophilic Archaeal Viruses <i>David Prangishvili, Mart Krupovic, and Diana P Baquero</i>	359
Euryarchaeal Viruses <i>Tatiana A Demina and Hanna M Oksanen</i>	368
Vesicle-Like Archaeal Viruses <i>Elina Roine and Nina S Atanasova</i>	380
Virus–Host Interactions in Archaea <i>Diana P Baquero, David Prangishvili, and Mart Krupovic</i>	387
Antiviral Defense Mechanisms in Archaea <i>Qunxin She</i>	400
Discovery of Archaeal Viruses in Hot Spring Environments Using Viral Metagenomics <i>Jennifer Wirth, Jacob H Munson-McGee, and Mark J Young</i>	407
Metagenomes of Archaeal Viruses in Hypersaline Environments <i>Fernando Santos, María D Ramos-Barbero, and Josefa Antón</i>	414
Extreme Environments as a Model System to Study How Virus–Host Interactions Evolve Along the Symbiosis Continuum <i>Samantha J DeWerff and Rachel J Whitaker</i>	419

Fungal Viruses

An Introduction to Fungal Viruses <i>Nobuhiro Suzuki</i>	431
Cross-Kingdom Virus Infection <i>Liyang Sun, Hideki Kondo, and Ida Bagus Andika</i>	443
Diversity of Mycoviruses in Aspergilli <i>Ioly Kotta-Loizou</i>	450
Evolution of Mycoviruses <i>Mahtab Peyambari, Vaskar Thapa, and Marilyn J Roossinck</i>	457
Mixed Infections of Mycoviruses in Phytopathogenic Fungus <i>Sclerotinia sclerotiorum</i> <i>Jiatao Xie and Daohong Jiang</i>	461
Mycovirus-Mediated Biological Control <i>Daniel Rigling, Cécile Robin, and Simone Prospero</i>	468
Mycoviruses With Filamentous Particles <i>Michael N Pearson</i>	478
Prions of Yeast and Fungi <i>Reed B Wickner and Herman K Edskes</i>	487
Single-Stranded DNA Mycoviruses <i>Daohong Jiang</i>	493
Structure of Double-Stranded RNA Mycoviruses <i>José R Castón, Nobuhiro Suzuki, and Said A Ghabrial[†]</i>	504

[†]Deceased.

<i>Ustilago maydis</i> Viruses and Their Killer Toxins <i>Alexis Williams and Thomas J Smith</i>	513
Vegetative Incompatibility in Filamentous Fungi <i>Songsong Wu, Daohong Jiang, and Jiatao Xie</i>	520
Viral Diseases of <i>Agaricus bisporus</i> , the Button Mushroom <i>Kerry S Burton and Greg Deakin</i>	528
Viral Killer Toxins <i>Manfred J Schmitt and Björn Becker</i>	534
Alternaviruses (Unassigned) <i>Hiromitsu Moriyama, Nanako Aoki, Kuko Fuke, Kana Takeshita Urayama, Naoki Takeshita, and Chien-Fu Wu</i>	544
Barnaviruses (Barnaviridae) <i>Peter A Revill</i>	549
Botybirnaviruses (Botybirnavirus) <i>Mingde Wu, Guoqing Li, Daohong Jiang, and Jiatao Xie</i>	552
Chrysoviruses (Chrysoviridae) - General Features and Chrysovirus-Related Viruses <i>Ioly Kotta-Loizou, Robert HA Coutts, José R Castón, Hiromitsu Moriyama, and Said A Ghabrial[†]</i>	557
Fungal Partitiviruses (Partitiviridae) <i>Eeva J Vainio</i>	568
Fusariviruses (Unassigned) <i>Sotaro Chiba</i>	577
Giardiavirus (Totiviridae) <i>Juliana Gabriela Silva de Lima, João Paulo Matos Santos Lima, and Daniel Carlos Ferreira Lanza</i>	582
Hypoviruses (Hypoviridae) <i>Dong-Xiu Zhang and Donald L Nuss</i>	589
Megabirnaviruses (Megabirnaviridae) <i>Yukiyo Sato and Nobuhiro Suzuki</i>	594
Mitoviruses (Mitoviridae) <i>Bradley I Hillman and Alanna B Cohen</i>	601
Mycoreoviruses (Reoviridae) <i>Bradley I Hillman and Alanna B Cohen</i>	607
Mymonaviruses (Mymonaviridae) <i>Daohong Jiang</i>	615
Narnaviruses (Narnaviridae) <i>Rosa Esteban and Tsutomu Fujimura</i>	621
Phlegiviruses (Unassigned) <i>Karel Petrzik</i>	627
Plant and Protozoal Partitiviruses (Partitiviridae) <i>Hanna Rose and Edgar Maiss</i>	632
Quadriviruses (Quadriviridae) <i>Hideki Kondo, José R Castón, and Nobuhiro Suzuki</i>	642
Totiviruses (Totiviridae) <i>Bradley I Hillman and Alanna B Cohen</i>	648

[†]Deceased.

Yado-kari Virus 1 and Yado-nushi Virus 1 (Unassigned) <i>Subha Das and Nobuhiro Suzuki</i>	658
Yeast L-A Virus (<i>Totiviridae</i>) <i>Reed B Wickner, Tsutomu Fujimura, and Rosa Esteban</i>	664
Algal Viruses	
Algal Marnaviruses (<i>Marnaviridae</i>) <i>Marli Vlok, Curtis A Suttle, and Andrew S Lang</i>	671
Algal Mimiviruses (<i>Mimiviridae</i>) <i>Ruth-Anne Sandaa, Håkon Dahle, Corina PD Brussaard, Hiroyuki Ogata, and Romain Blanc-Mathieu</i>	677
Miscellaneous Algal Viruses (<i>Alvernaviridae, Bacilladnaviridae, Dinodnavirus, Reoviridae</i>) <i>Keizo Nagasaki, Yuji Tomaru, and Corina PD Brussaard</i>	684
Phycodnaviruses (<i>Phycodnaviridae</i>) <i>James L Van Etten, David D Dunigan, Keizo Nagasaki, Declan C Schroeder, Nigel Grimsley, Corina PD Brussaard, and Jozef I Nissimov</i>	687
Invertebrate Viruses	
An Introduction to Viruses of Invertebrates <i>Peter Krell</i>	699
Ascoviruses (<i>Ascoviridae</i>) <i>Sassan Asgari, Dennis K Bideshi, Yves Bigot, and Brian A Federici</i>	724
Baculovirus–Host Interactions: Repurposing Host-Acquired Genes (<i>Baculoviridae</i>) <i>A Lorena Passarelli</i>	732
Baculoviruses: General Features (<i>Baculoviridae</i>) <i>Vera ID Ros</i>	739
Baculoviruses: Molecular Biology and Replication (<i>Baculoviridae</i>) <i>Monique M van Oers</i>	747
Bidensovirus (<i>Bidnaviridae</i>) <i>Qin Yao, Zhaoyang Hu, and Keping Chen</i>	759
Bunyaviruses of Arthropods (<i>Myxoviridae, Nairoviridae, Peribunyaviridae, Phasmaviridae, Phuniviridae, Wupedeviridae</i>) <i>Sandra Junglen</i>	764
Dicistroviruses (<i>Dicistroviridae</i>) <i>Yanping Chen and Steven M Valles</i>	768
Entomobirnaviruses (<i>Birnaviridae</i>) <i>Marco Marklewitz</i>	776
Hytroviruses (<i>Hytroviridae</i>) <i>Henry M Kariithi and Irene K Meki</i>	780
Iflaviruses (<i>Iflaviridae</i>) <i>Bryony C Bonning and Sijun Liu</i>	792
Iridoviruses of Invertebrates (<i>Iridoviridae</i>) <i>İkbal Agah İnce</i>	797
Mesoniviruses (<i>Mesoniviridae</i>) <i>Jody Hobson-Peters and Daniel Watterson</i>	804

Nimaviruses (<i>Nimaviridae</i>) <i>Peter Krell and Emine Ozsahin</i>	808
Nodaviruses of Invertebrates and Fish (<i>Nodaviridae</i>) <i>Kyle L Johnson and Jacen S Moore</i>	819
Nudiviruses (<i>Nudiviridae</i>) <i>Yu-Chan Chao, Chih-Hsuan Tsai, and Sung-Chan Wei</i>	827
Parvoviruses of Invertebrates (<i>Parvoviridae</i>) <i>Judit J Péntzes, Hanh T Pham, Qian Yu, Max Bergoin, and Peter Tijssen</i>	835
Polydnaviruses (<i>Polydnaviridae</i>) <i>Anne-Nathalie Volkoff and Elisabeth Huguet</i>	849
Poxviruses of Insects (<i>Poxviridae</i>) <i>Basil Arif, Lillian Pavlik, Remziye Nalçacıoğlu, Hacer Muratoğlu, Cihan İnan, Mehtap Yakupoğlu, Emine Özşahin, İsmail Demir, Kazım Sezen, and Zihni Demirbağ</i>	858
Reoviruses of Invertebrates (<i>Reoviridae</i>) <i>Peter Krell</i>	867
Rhabdoviruses of Insects (<i>Rhabdoviridae</i>) <i>Andrea González-González, Nicole T de Stefano, David A Rosenbaum, and Marta L Wayne</i>	883
Sarothroviruses (<i>Sarothroviridae</i>) <i>Azeez Sait Sahul Hameed</i>	888
Solinviviruses (<i>Solinviviridae</i>) <i>Steven M Valles and Andrew E Firth</i>	892
Tetraviruses (<i>Alphatetraviridae, Carmotetraviridae, Permutotetraviridae</i>) <i>Rosemary A Dorrington, Tatiana Domitrovic, and Meesbah Jiwaji</i>	897

FUNDAMENTALS OF VIROLOGY

A Brief History of Virology

David J Rowlands, University of Leeds, Leeds, United Kingdom

© 2021 Elsevier Ltd. All rights reserved.

Introduction

Virology is a relatively young scientific discipline, having only come into its own in the late 1900s and the early decades of the 20th century. However, it has had an enormous influence on most aspects of biological science and continues to do so until this day. The importance of virology in the evolution of the life sciences is reflected by the number of Nobel Prizes that have been awarded for work of direct or indirect impact on the field ([Table 1](#)). The study of viruses has been integral to the development of our understanding of the chemical and physical bases of life, the underlying principles of genetics, the immense complexity of host defense mechanisms and the power viruses have to influence even global phenomena such as the climate.

Viruses have profoundly affected humanity for millennia. Changes in the size and structure of human populations have almost certainly influenced our relationships with viruses. At the dawn of humanity small family based groups of hunter/gatherers were probably insufficient for the maintenance of many highly transmissible viruses due to rapid exhaustion of the susceptible host population. Exceptions may be viruses that can initiate persistent infections, e.g., tumor viruses (papillomaviruses, retroviruses, herpesviruses). It is likely that expansion of the human population and development of societal lifestyles provided suitable sized host pools to allow continued transmission of viral pathogens across more integrated populations. Modern sequence and bioinformatics based epidemiological studies have revealed the frequency with which viruses cross between species, allowing them to continuously sample the potential host pool.

Given the limitation of space, this introductory article can provide only a brief overview of the rich history of the origins and evolution of virology. Unfortunately, there is not enough space to acknowledge the many individuals who have contributed to the science of virology. It will necessarily paraphrase and précis many other treatise that cover the subject in greater depth. A list of selected historical highlights during the development of the science of virology is given in [Table 2](#).

Previrology

Diseases of plants, animals and humans had been observed for centuries but it was not until the latter half of the 19th century that progress was made in understanding their underlying causes. Transmissible infections had been observed since times of antiquity, as had the realization that recovery from disease could result in resistance against reinfection. This is well illustrated by the story of smallpox, control of which was initially attempted by the ancient and dangerous practice of variolation and finally by the more controlled process of vaccination developed in the 18th century by Edward Jenner. The germ theory, as proposed by Pasteur, contributed enormously to the concept that diseases were caused by definable agents as opposed to “acts of god”, poisons and miasmas. Demonstration that infectious agents could be grown *in vitro* led Koch to propose the defining characteristics necessary to confirm the causative agent of an infectious disease. These are the famous Koch’s postulates that state:

- (1) The microorganism must be found in abundance in all organisms suffering from the disease, but should not be found in healthy organisms.
- (2) The microorganism must be isolated from a diseased organism and grown in pure culture.
- (3) The cultured microorganism should cause disease when introduced into a healthy organism.
- (4) The microorganism must be re-isolated from the inoculated, diseased experimental host and identified as being identical to the original specific causative agent.

These criteria were useful for defining the etiological agents of diseases caused by cultivatable bacteria and fungi but it became apparent that for many diseases all of the requirements could not be fulfilled, such as the ability to cultivate the causative agents *in vitro*. In addition, for an increasing number of diseases the causative agents were shown not to be removed by filtration through porcelain filters, such as the Chamberland filter candle, and were therefore significantly smaller than bacteria.

Dawn of Virology

The first demonstration that disease could be transmitted by agents other than bacteria was made in 1882 by Mayer, who showed that mechanical transmission of soluble extracts from tobacco plants affected by a mosaic disease to fresh plants resulted in their developing the disease. However, no causative agent for the disease could be cultured *in vitro*. Subsequently, Ivanovsky in 1892 showed that the ability of such extracts to transmit disease was not removed by passing through a filter candle capable of removing known bacteria. This observation was repeated by Beijerinck in 1898 who also made the key finding that the disease causing agent could be recovered following dilution and was, therefore, capable of reproduction and differed

Table 1 Nobel prizes awarded for work of relevance to virology

<i>Year</i>	<i>Laureate</i>	<i>Category</i>	<i>Subject</i>
1905	Robert Koch	Physiology or Medicine	Discoveries relating to Tuberculosis
1951	Max Theiler	Physiology or Medicine	Yellow Fever
1954	John Enders Thomas Weller Frederick Robbins	Physiology or Medicine	Growth of poliovirus in tissues culture
1958	Joshua Lederberg	Physiology or Medicine	DNA transduction in bacteria
1965	Francois Jacob Andre Lwoff Jacques Monod	Physiology or Medicine	Genetic control of enzyme and viral synthesis
1966	Peyton Rous	Physiology or Medicine	Discovery of tumor viruses
1969	Max Delbruck Alfred Hershey Salvador Luria	Physiology or Medicine	Replication mechanisms and genetic structure of viruses
1975	David Baltimore Renato Dulbecco Howard Temin	Physiology or Medicine	Interaction between tumor viruses and cellular genetic material
1976	Baruch Blumberg Carleton Gajdusek	Physiology or Medicine	Discoveries of new mechanisms for origin and dissemination of infectious diseases
1978	Werner Arber Daniel Nathans Hamilton Smith	Physiology or Medicine	Discovery of restriction enzymes and their application to molecular genetics
1982	Aaron Klug	Chemistry	Crystallographic electron microscopy and elucidation of RNA/protein complexes
1984	Niels Jerne Georges Kohler Cesar Milstein	Physiology or Medicine	Discoveries on the control of the immune system and the production of monoclonal antibodies
1986	Ernst Ruska Gerd Binnig Heinrich Rohrer	Physics	Development of electron and scanning tunneling microscopes
1988	James Black Gertrude Elion George Hitchings	Physiology or Medicine	Drug discovery
1989	Michael Bishop Harold Varmus	Physiology or Medicine	Cellular origin of retroviral oncogenes
1993	Richard Roberts Phillip Sharp	Physiology or Medicine	Discovery of split genes
1993	Kary Mullis	Chemistry	Invention of PCR
1996	Peter Doherty Rolf Zinkernagel	Physiology or Medicine	Cell mediated immunity
2008	Harald zur Hausen	Physiology or Medicine	Human papillomavirus and cervical cancer
2008	Francoise Barre-Sinoussi Luc Montagnier	Physiology or Medicine	Discovery of HIV
2017	Jacques Dubochet Joachim Frank Richard Henderson	Chemistry	Cryo-electron microscopy
2018	George Smith Gregory Winter	Chemistry	Phage display of peptides and antibodies

fundamentally from inert poisons. He was also the first to adopt the term virus, from the Latin for slime or poison. This work is often heralded as the birth of virology, a new branch of biology which would expand in the coming century to have major impacts on the study and understanding of virtually all aspects of the life sciences. Other than being very small, the nature of this new infectious agent was not properly understood for many years and was referred to as “*contagium vivum fluidum*”, referring to its apparently non-particulate or fluid nature.

Table 2 Selected historical highlights in virology

Year	Highlight	Investigators
1892	Filterable infectious agent (Tobacco Mosaic Virus - TMV)	Ivanovsky
1898	Concept of virus (TMV)	Beijerinck
1898	First animal virus (FMDV)	Loeffler & Frosch
1901	First human virus (Yellow Fever Virus)	Reed
1911	First solid tumor virus (Rous sarcoma virus)	Rous
1915	First bacterial viruses	Twort
1917	First bacterial virus plaque assay	D'Herelle
1935	Crystallization of TMV	Stanley
1938	Development of electron microscope	Ruska. <i>et al.</i>
1939	First description of single step bacteriophage growth cycle	Ellis, Delbruck
1952	Demonstration that nucleic acid is determinant of infection	Hershey, Chase
1955	<i>In vitro</i> assembly of TMV	Fraenkel-Conrat, Williams
1940s – 50s	Development of tissue culture for in vitro culture and study of viruses	Enders, <i>et al.</i>
1957	Discovery of interferon	Isaacs, Lindenmann
1959	Development of negative stain EM	Brener, Horne
1962	Principles of virus structure	Caspar, Klug
1950–1970	Origins and expansion of molecular virology	numerous
1970–2000	Origins and expansion of cellular immunity	numerous
1970	Discovery of retrovirus reverse transcriptase	Temin, Baltimore
1976	First RNA virus sequence (MS2)	Fiers
1977	First DNA virus sequences (ϕX174, SV40)	Sanger, Fiers, Weissman
1977	Eradication of Smallpox	WHO
1978	First plant virus structure (tomato bushy stunt virus)	Harrison
1983	Discovery of human immunodeficiency virus (HIV)	Montagnier, Barre-Sinoussi, Gallo
1985	First animal virus structures (rhinovirus, poliovirus)	Rossmann, Hogle
1989	First virus discovery by molecular biology techniques (HCV)	Houghton. <i>et al.</i>
1998	Suppressor RNAi in plants	Vance, Baulcombe
2002	SARS coronavirus zoonotic transfer and epidemic	global
2009	Influenza H1N1 pandemic	global
2011	Eradication of rinderpest	OIE
2014	Ebola epidemic – West Africa	
2019	SARSCoV-2 pandemic	global

Thus the first pathogen to be classified as a virus was the etiological agent of a disease of plants; tobacco mosaic virus (TMV). The first animal virus found to pass through bacteria retaining filters was that responsible for foot-and-mouth disease (FMD). This observation was made by Loeffler and Frosch in 1897 in studies to identify the cause of a devastating epidemic disease of cattle that had been recorded as long ago as 1546 by Hieronymus Fracastorius. The origins of bacterial virology dates back to a similar period when an agent present in waters of the river Ganges which destroyed *Vibrio cholera* cultures was shown by Ernest Hankin in 1889 to pass through bacterial filters. In 1901, Walter Reed showed that the causative agent of yellow fever could also pass through a bacterial filter and was the first human pathogen to be classified as a virus by this criterion. Apart from the ability to pass through filters the physical and chemical natures of these new entities were not understood. An important step forward was the demonstration by d'Herelle in 1917 that the bacterial viruses could be quantified by counting the number of plaques (clear areas of cell destruction) that were formed on bacterial lawns. This graphically demonstrated that the infectious agents were particulate and could replicate.

These early observations defined the basic characteristics of viruses and in the first decades of the 20th century the number and variety of infectious agents belonging to this category of pathogens expanded almost exponentially, a phenomenon that continues to this day. As the range of physical and chemical techniques available to interrogate the structure and function of the viruses expanded, it became apparent that, collectively, they included all conceivable ways of storing and expressing genetic information.

The development of virology in the 20th century can be roughly considered as a series of sequential but often overlapping phases, largely driven by characteristics of the host/virus interactions and by technological advances. The original observations that a number of pathological agents infecting plants, animals, and bacteria shared the properties of being smaller than any known bacteria and being non-cultivable *in vitro* begged the question of their nature. Resolving the fundamental nature and function of viruses occurred during the end of the 19th and early decades of the 20th centuries and thereafter expanded rapidly.

The Physico-Chemical Phase – Plant Viruses

Plant virology played an important role in the early stages of unraveling the chemical and physical properties of viruses. In particular, studies of TMV were instrumental in resolving many of the key features of viruses. Growth to high levels in infected plants, ease of

purification and stability of the virus made it an ideal candidate for detailed study. Chemical and physical studies showed that the infectious agent shared many of the properties of proteins, including the ability to induce and be neutralized by antibodies. More detailed chemical analysis suggested that the virus was composed of 95% protein and 5% nucleic acid. The observation that different symptoms could be induced by different viral isolates indicated their genetic nature. Demonstration of the property of birefringence indicated that the infectious agent was large, in molecular terms, and asymmetrical in shape. These properties were confirmed when purified virus particles were first crystallized and then directly observed in the electron microscope in 1939, the first visualization of a virus particle. X-ray diffraction analysis indicated regular hexagonal arrangement and, subsequently, dissociation and reassembly of virus particles in vitro showed them to be composed of multiple copies of components with the inherent ability to self-assemble.

The Biochemical Phase – Bacterial Viruses

The inherent properties of many plant viruses (e.g., TMV) of high level growth and stability accounts for their important roles in unraveling the basic nature and structure of viruses. Bacteria had also been shown to be susceptible to infectious agents with similar properties to viruses. Frederick Twort is accredited with the discovery of bacterial viruses in 1915 when he described the “glassy transformation” of bacterial cultures by a filterable and dilutable agent. Shortly after, d’Horelle made similar observations and introduced the term bacteriophage (bacteria eater). In addition to again demonstrating the filtration resistance of viruses, he developed the first method of quantifying the infectious particles by counting the clear plaques they produced on bacteria culture plates. These studies heralded a number of important advances including the demonstration that bacteriophages attached to their hosts via specific receptor interactions. The phenomenon of lysogeny was also described, in which the bacteriophage genome could remain quiescent within the host and remain associated during bacterial replication but to re-emerge as a lytic infection under appropriate conditions. The dimensions and chemical composition (e.g., DNA, as opposed to RNA in TMV) of bacteriophages were also studied throughout this period.

Two great advantages of bacteriophages for study are the speed with which replication occurs (minutes as opposed to hours or days in other systems) and the ability to infect cultures simultaneously and so study one-step growth kinetics. These properties opened the doors to investigating the very nature of genetic inheritance and expression. The study of bacteriophages in the 1940s and 50s laid the foundations for understanding how viruses replicate which, in turn, established many of the most important aspects of cell function. Many of these ground-breaking discoveries were made by members of the famous “phage group” who first convened at Cold Spring Harbor in 1947. Seminal discoveries made by some of the giants in the field, such as Cohen, Chargaff and Stanley included the demonstration of massive and synchronised biochemical and macromolecular changes in the infected cell during the eclipse phase between initiation of infection and the assembly of new phage particles. Dramatic changes in RNA and DNA synthesis in the infected cells occurred during a period of a few minutes. In addition, it was found that a cellular enzyme was inhibited, thus illustrating the profound changes in cellular function as a consequence of infection. These studies led ultimately to the concept of messenger RNA being the intermediary for gene expression.

A key experiment conducted in 1952 by Hershey and Chase demonstrated that DNA was the molecule responsible for initiating the infectious cycle and is the cornerstone of genetic inheritance. They infected bacteria with phage particles differentially radioactively labeled in protein and DNA and showed that while the protein component remained at the surface and could be removed mechanically after infection had occurred, the DNA was internalized into the bacterial cells. That DNA is the repository of genetic information was further confirmed by Wyatt and Cohen who showed that phage infected bacteria expressed a novel enzyme activity not found in uninfected cells and which therefore must be encoded by the phage genome.

In 1949, Lwoff showed that the genomes of certain DNA phages were incorporated into host cell genomes to induce the lysogenic state, whereby the phage genome is replicated as a component of the host DNA but can be released as an independently replicating lytic phage following environmental stimuli. These phenomena clearly have parallels in the ability of many eukaryotic viruses to integrate into host genomes to initiate oncogenic consequences. The phenomenon of lysogenic integration of phage genome into the host chromosome allowed for genetic mapping of the phage genome. This was achieved by synchronized interruption of bacterial mating to control the proportion of the phage genome transferred to the recipient bacterium during conjugation.

Study of T4 (a lytic phage) and λ (a temperate phage) in particular established the fundamental nature of genetic structure and inheritance. However, an ever expanding number of bacteriophages were discovered which did not conform to the paradigm of double stranded DNA being the sole mechanism for storage and expression of genetic information. Bacteriophages with single stranded DNA and even RNA genomes were discovered, thus exposing the array of alternative lifestyles adopted by viruses. A theme that was further explored by the study of animal viruses.

The Cell Biology Phase – Animal Viruses

The identification and investigation of animal viruses was, and still is, dominated by their involvement in pathogenesis. However, their study has contributed enormously to our basic understanding of the molecular basis of eukaryotic cell function. Although mammalian viral diseases had been recognized for millennia, e.g., smallpox, polio, rabies, foot-and-mouth disease, it was not until the end of the 19th and beginning of the 20th century that the nature of the causative agents was rigorously investigated. Careful use of size specific filters together with investigation of the susceptibility of the infectious agents to exposure to physical and

chemical challenges help to define their basic characteristics. Many important features of the ever increasing array of viruses were demonstrated in these earlier studies. As a few examples, seminal investigations by Walter Reed showed that yellow fever virus (YFV) is transmitted by an insect vector (mosquito), different cell susceptibilities were demonstrated as were the varying outcomes of infection by different viruses, for instance chronic or persistent infection, cell destruction or cell proliferation and oncogenesis.

A major factor that revolutionized the study of animal viruses was the development of in vitro culture of living tissues and cells. Initially primary isolates of cells from susceptible tissues could be cultured for limited periods but a real breakthrough came in 1951 with the selection of the human carcinoma cell line, HeLa, which could be cultured and amplified indefinitely. Subsequently, many other cells lines have been developed and successfully used to facilitate virus research. The advent of cell culture techniques was not only of benefit to fundamental virology research, it also paved the way for vaccine development. The first vaccine against polio was developed by Jonas Salk in 1952 and was made possible by the ability to grow industrial scale quantities of HeLa cells. This massive achievement was made possible by a huge publically funded research project (the March of Dimes) and resulted in the elimination of the annual epidemics of paralytic poliomyelitis that had become the scourge of summer months in the developed world.

The study of viral growth cycles resulted in the discovery of many features of cell biology which underpin our current understanding of cellular functions. For example, understanding the control of gene expression and the role of enhancers evolved through the study of SV40 in the early 1980s. Study of the perturbation of normal cellular replication control mechanisms following integration of viral genes were important for understanding oncogenic transformation. Research on different viruses during the 1980s and 90s provided details of mRNA expression and processing such as mRNA splicing (adenovirus), polyadenylation (pox viruses) and mRNA capping (reoviruses).

Viral Diversity

As more viruses were discovered and characterized the remarkable range of their genome organization became apparent and in 1971 Baltimore proposed a system of classification based on the fundamental nature of viral genomes:

- (1) Double stranded DNA genomes, as in normal cellular organisms.
- (2) Single stranded DNA genomes with +ve (mRNA) sense polarity.
- (3) Double stranded RNA genomes.
- (4) Single stranded RNA genomes with +ve strand polarity.
- (5) Single stranded RNA genomes with -ve strand polarity.
- (6) Single stranded RNA genomes with conversion to DNA during the replication cycle.

In addition to this remarkable array of molecular mechanisms adopted by viruses to store and express their genetic information, genomes were found to be contained within a single molecule or divided into multiple segments, especially in viruses belonging to groups (3), (4) and (5).

As well as this diversity of genetic structure, virus particles were found to display an array of morphologically distinct structural types of widely different complexities. Viral genomes were found to be encapsidated in either of two structural types. The first virus for which structural data was determined (TMV) showed regular helical symmetry, occurring as elongated rods, the dimensions of which were dictated by the length of the genomic RNA. In 1955 it was shown by Fraenkel-Conrat and Williams that separated protein subunits and RNA molecules would reassemble into infectious particles indicating that the structural rules dictating self-assembly were present entirely within the viral components alone. The other major structural theme was encapsidation of the genome within a protein shell of cubic (icosahedral) symmetry. The dimensions of icosahedral nucleocapsids could be varied to accommodate different sized genomes by "simply" varying the number of protein subunits. The principles of icosahedral virus symmetry were determined by Caspar and Klug in 1962. The number of sub-units present in a $T = 1$ icosahedral particle is 60, in which all subunits are in chemically identical environments. For larger icosahedral particles with greater numbers of identical subunits they cannot occupy chemically identical environments, which led to the important concept of quasi-equivalence in which the relationships between different protein subunits within the structure are similar, but not identical. Although these basic "design features" were found to apply generally across the vast spectrum of viruses many often complex modifications and additions to the basic structural motifs were discovered. For example, DNA phages were found to have complex tail structures involved in attachment to the bacterial cell and delivery (injection) of the viral genome. In addition to the proteins directly required for viral assembly and structure it was shown that many viruses obligatorily include enzymes, such as polymerases necessary for transcription of -ve strand RNA genomes into the +ve form necessary for protein translation and the initiation of infection.

Many viruses were found to be wrapped in one (or more) lipid envelopes bearing membrane anchored glycoproteins associated with cell binding and entry through membrane fusion. The presence or absence of an outer membrane envelope was a crucial determinant of the sensitivity of viruses to membrane destroying agents, such as detergents.

The full spectrum of viral diversity has expanded beyond imagination since the identification of TMV and FMDV c.130 years ago. The known virome ranges from viroids, small circular single-stranded replicating RNA pathogens of plants discovered in 1971, to relatively gigantic examples such as the mimiviruses discovered in 2003. Viruses are the most abundant organisms on earth – it is estimated that the world's oceans contain some 10³⁰ viruses, and their influence can be seen globally. They can influence the distribution of phytoplankton and consequently nutrients leading to global changes in atmospheric gasses.

The Structural Phase

As is the case with all scientific disciplines, progress in the study of viruses was dependent on and driven by technological innovation. The dawn of virology as an independent discipline was heralded by the apparently simple procedure of size discrimination by selective filtration, e.g. the initial studies of TMV, FMDV and YFV referred to above.

The invention of the electron microscope in the late 1930s enabled visualization of the TMV particle, for the first time in 1939. EM images confirmed the expectation derived from X-ray analysis of the crystals of the virus, showing that the particles were rod shaped and of defined diameter. Further development and refinement of the electron microscope and improvements in sample preparation and treatment heralded a rich period in the 1970s and 1980s of virus identification and morphological classification. During this period electron microscopy played a major role in the identification and epidemiology of viral infections. In fact, it still has an important role in the identification of viruses which cannot be cultured easily *in vitro*, such as many enteric viruses, and was used to identify coronaviruses as the agents responsible for the recent zoonotic transfer and pandemic spread of SARS-CoV-2.

X-ray crystallography developed steadily during the 20th century and for several decades it was the only technique able to generate structural information on viruses at near atomic resolution. The first icosahedral virus for which this level of structure determination was achieved was tomato bushy stunt virus in 1978 by Harrison and colleagues. The first animal virus structures to be determined at similar resolution were the picornaviruses human rhinovirus and poliovirus in 1985 by Rossmann and Hogle, respectively. The size and complexity of viruses that could be examined in this detail continued to increase as the technology developed. For example, the structure of blue tongue virus, which has $20\times$ greater diameter than picornaviruses, was resolved in the late 1990s by Stuart *et al.* In favorable circumstances, viruses could be co-crystallized in complex with their cell receptors, antibodies or antiviral inhibitors, with important consequences for drug and vaccine design and the understanding of virus attachment to host cells. Despite the tremendous advances in understanding virus structure made possible by X-ray crystallography, the method is restricted by some unavoidable constraints. For example, only structures which can be crystallized are available for study, which eliminates pleomorphic structures typical of many enveloped viruses. Secondly, structures of virus particles could only be analyzed when regularly ordered in the crystalline state, making the study of dynamic and irregular intermediate particles (for example during cell entry) impossible. Electron microscopy had the potential to overcome some of these restrictions but, until recently, did not have the resolving power to study viruses at the atomic level. Enormous advances in cryo-electron microscopy in recent years have overcome these restrictions with the result that the technique has largely superseded X-ray crystallography as the principle method for high resolution structure determination. Tomographic cryo-electron microscopy has the added advantage of facilitating analysis of viruses and virus-induced structures within cells. It is adding greatly to our understanding of viral functions such as the infection process, virus replication, cellular remodeling, and the process of assembly and maturation of new viral particles.

The Sequencing Phase

The 1970s saw the start of the nucleotide sequencing revolution which has come to underpin many areas of biology. The first RNA virus to be sequenced was the bacteriophage MS2 by Walter Fiers group in 1976. This was a major achievement and depended on the isolation and analysis of fragments of radioactively labeled genome generated by specific RNase digestion. The generation of strain specific fragment profiles by RNase T1 has also been used as a sensitive method for discriminating epidemic virus strains. Development of the di-deoxynucleotide chain termination nucleotide sequencing technology by Fred Sanger and colleagues allowed the determination of the first complete genome sequence of a DNA virus, the bacteriophage ϕ X174, in 1977. This method greatly simplified nucleotide sequencing and when coupled with retroviral reverse transcriptase it was readily applicable to RNA viruses. These technical improvements, together with plasmid cloning of DNA fragments produced by restriction enzyme digestion, greatly accelerated and simplified determination of viral nucleic acid sequences. The invention of the polymerase chain reaction (PCR) in 1983 by Mullis added another strong arm to the arsenal of techniques available for understanding and manipulating viral genomes and has become of great importance in viral diagnostics. Finally, development of Next Generation Sequencing technology, in which parallel sequencing of millions of random DNA fragments coupled with the computational methods to combine the reads to obtain the original DNA sequence has increased sequencing power such that complete eukaryotic genomes can be determined in a single day. The sophistication of these technical advances is such that sequence information derived from random genome fragments representing mixtures of multiple organisms can be sorted into individual species. The application of these methodologies has demonstrated the enormous diversity of viruses in environmental samples, such as sea water, without the requirement for individual virus isolation or characterization.

Cloning, *in vitro* manipulation and sequencing of DNA have enabled a number of major developments in virology. The first demonstration that a virus could be recovered from cloned DNA was the bacteriophage Q β in 1978 and in 1981 poliovirus was recovered from HeLa cells transfected with a bacterial plasmid containing a cloned cDNA copy of the viral genome. Subsequently, poliovirus was recovered from a chemically synthesized DNA copy of the genome. In subsequent years *in vitro* manipulation of viral genomes has been used extensively for a variety of reasons. For example, recombinant adenoviruses have been constructed as potential gene therapy agents to replace faulty genes in conditions such as cystic fibrosis. Similarly, recombinant viruses such as insect baculoviruses are widely used to express large quantities of protein products, such as the coat proteins of human papilloma viruses for use as vaccines. DNA manipulation techniques have also been used to develop recombinant viruses for use as live virus vaccines. A notable recent example is a vaccine derived from an attenuated vesicular stomatitis virus which has been manipulated to express the

surface glycoprotein of ebola virus. This novel vaccine was developed and approved for use in record time to join other recombinant ebola vaccines based on adenovirus and vaccinia virus to combat the devastating epidemic of ebola in West Africa in 2014–16.

Pathogenicity and Host Defense Mechanisms

As intracellular parasites, viruses encounter a plethora of host defense mechanisms. The phenomenon of *E. coli* strain specific restriction of phage λ growth was discovered in the 1950s in the laboratories of Luria, Weigle and Bertani; in the 1960s, the endonuclease enzymes responsible for this bacterial immunity were described. Subsequently many thousands of restriction enzymes with different sequence specificities were discovered and became invaluable tools in the explosion of genetic analysis and manipulation that followed. Restriction enzymes are the bacterial equivalent to the innate or non-adaptive responses found in eukaryotes. A prokaryotic adaptive immune response system (CRISPR) was first described in 2005 following two decades of analyses of bacterial genomes including repeat sequence regions. In 2012, modifications of the CRISPR Cas9 system were reported which facilitated the defined manipulation by site specific insertion of DNA sequences into genomes of any organism. This system, derived from bacterial antiviral adaptive immune mechanisms, is now widely used in many areas of biology from the development of crop plants to the manipulation of mosquito genomes.

Equivalent non-adaptive (innate) and adaptive antiviral protective immune systems were also discovered in plants. Receptors able to recognize PAMPs (pathogen associated molecular patterns) were discovered in the 2000s and signaling via these receptor mechanisms induces the expression of a number of genes which affect an antiviral state in the infected cells. Plants were also shown to develop adaptive responses to viral infections by the production of short anti-viral RNA molecules targeted to and able to silence invading viral RNAs.

The ability of humans and other animals to acquire immunity to viruses was well known from the smallpox and rabies vaccination work of Jenner and Pasteur in the 18th and 19th centuries, respectively. Acquired immunity is associated with factors present in serum and can be transferred to naïve animals, as was demonstrated in the late 19th century by Behring and Kitasato. Work in subsequent decades identified antibodies as the serum components responsible for protection, culminating in the resolution of antibody structure in the 1960s and 70s by Edelman, Porter and others. Another milestone was achieved in the 1970s by Milstein *et al.* with the development of techniques to isolate and produce unlimited quantities of monoclonal antibodies. These reagents have proved invaluable in many fields of virology including therapy and diagnostics.

The complex roles of T cells in the evolution of both humoral and cell mediated adaptive antiviral responses were elucidated during the 1970s and 80s. The Nobel Prize winning work by Zinkernagel and Doherty on lymphocytic choriomeningitis virus in mice showed the importance of major histocompatibility (MHC) molecules in the induction and selection of specific anti-viral cytotoxic T cells. Viruses have been key to unraveling the complex interplay between the innate and adaptive arms of the immune system. The discovery of interferon, a soluble factor produced by infected cells and able to induce an antiviral state in naïve cells, by Alick Isaacs in 1957 opened the door to the eventual unraveling of the complicated controls and operations of innate immunity in animal systems.

A number of receptors able to detect foreign (e.g., viral) molecules (PAMPs) were found to induce expression of anti-viral defense proteins via intracellular signaling pathways. The complex interplay between viruses and their mammalian hosts has been a rich field of investigation, especially in the latter decades of the 20th century and into the 21st. Viruses have been found to have evolved numerous mechanisms of avoidance of both innate and adaptive immune responses. It had long been known that escape from humoral, antibody mediated, host defense is acquired largely by antigenic mutation. Influenza provided a prime example with the well-studied phenomena of antigenic drift through sequential acquisition of point mutations and antigenic shift by genome segment exchange. More recently a variety of mechanisms for abrogating and bypassing both adaptive and innate immune defenses have been discovered. For instance, herpes viruses can inhibit the presentation of MHC molecules at the plasma membrane, thus rendering infected cells invisible to cytotoxic T cells. Many viruses, such as HCV, can disrupt the intracellular signaling pathways involved in the induction of IFN; poxviruses produce many “molecular decoys” such as soluble equivalents of host cell-surface linked IFN receptors.

Epidemiology

Diagnostic methods underpin epidemiological studies and progressive improvements in the speed and accuracy of diagnostic techniques have been key to understanding and controlling the spread of viral diseases. In the earlier and mid decades of the 20th century clinical observation was supported by morphological characterization using EM and by immunofluorescence methods and an increased use of primary tissue culture and eventually immortal cell lines.

The development of serological techniques for the detection of viruses, such as complement fixation tests in the 1920s and haemagglutination tests in the 1940s greatly increased the speed and accuracy of viral diagnostic procedures. In the 1970s the enzyme-linked immunosorbent assay (ELISA) largely superseded other serological techniques for rapid laboratory based investigations. The invention of the polymerase chain reaction (PCR) in 1983, together with advances in nucleic acid sequencing techniques again greatly advanced accuracy and sensitivity of diagnostic procedures. Development of deep-sequencing techniques in the 21st century have facilitated epidemiological investigations at unprecedented levels of accuracy, allowing detailed investigations of the spread of viral infections during epidemics.

Table 3 Selected milestones in vaccine development

Year	Virus	Vaccine type	Principle investigators
1798	Smallpox	Attenuated	Jenner
1885	Rabies	Attenuated/inactivated	Pasteur
1938	Yellow fever	Attenuated	Theiler
1945	Influenza	Inactivated	Francis, Salk. <i>et al.</i>
1947	Foot-and-mouth disease	Inactivated (primary tissue)	Fraenkel
1952	Polio	Inactivated	Salk
1957	Polio	Attenuated	Sabin, Koprowski
1962	Foot-and-mouth disease	Inactivated (cell culture)	Mowat, Capstick. <i>et al.</i>
1971	Measles, mumps, rubella	Attenuated	Hilleman
1984	Hepatitis B	Recombinant (VLPs)	Valenzuela
1994	Hepatitis A	Inactivated	Innis
2006	Human papilloma	Recombinant (VLPs)	Cervarix and Gardasil
2019	Ebola	Recombinant (vectored)	Feldmann

Viral Control

Vaccines

Antiviral vaccines have alleviated the burden of many viral diseases of both humans and livestock and have contributed to the total eradication of two important disease; an enormous achievement for mankind. A summary of some of the historical highlights of vaccine development are shown in [Table 3](#).

The origins of vaccination predate the birth of virology as a defined discipline. Variolation was developed in China in the 15th century to protect against the devastating disease of smallpox. It involved infecting the patient by rubbing infectious material from pox lesions onto scarified skin to induce a less severe disease than when the infection was acquired naturally. In 1796 Edward Jenner adapted the same technique but used pustular material from a milkmaid thought to have acquired the infection from a cow. The cowpox was, in effect, a naturally attenuated virus in humans. Although farmers were aware of this method to protect against smallpox, Jenner formally tested the effectiveness of the procedure by challenging a vaccinated boy with virulent smallpox. His insight and dedication led ultimately to the declaration of the eradication of smallpox in 2004, the first disease to be eliminated. The next viral immunization procedure was developed almost a century later in 1885 when Pasteur vaccinated a boy who had been bitten by a rabid dog with material derived from the brain of a rabbit infected with rabies. The material had been “weakened” by drying and was, in effect, a combined attenuated and inactivated antiviral vaccine.

Developments in culture of primary cells *in vitro* in the 1930s and 40s facilitated isolation of a number of important viruses. Yellow fever vaccine was the first to be derived by multiple sequential passage until a non-pathogenic strain had been selected. Some killed vaccines were also produced during these years; for example, influenza was grown in embryonated eggs and chemically inactivated with formaldehyde. FMDV vaccines were produced by growth in epithelial tissue stripped from the tongues of slaughtered cattle and inactivated with formaldehyde. The difficulties and disadvantages of culturing cells from primary tissues were overcome by the selection of immortal cell lines. The first was the HeLa cell line, named after Henrietta Lacks, a cervical cancer patient from whom the cells were obtained in 1951, which enabled the development of the Salk inactivated vaccine against poliovirus. Tissue culture enabled the development and production of virus vaccines in sufficient quantities to conduct mass vaccination campaigns. Many live attenuated or chemically inactivated vaccines were developed using “classical” *in vitro* cell culture in the 1960s–1980s including, for example, measles, mumps, rubella, rabies and hepatitis A. Controlled use of vaccines has resulted in the global eradication of two viral diseases; smallpox in 1980 and the rinderpest in 2011. Rinderpest virus caused periodic devastating plagues in cattle and other ungulates for millennia in Asia, Europe and more recently Africa, and was eliminated using an attenuated vaccine developed by Plowright in the 1960s.

Molecular techniques have been applied in the later decades of the 20th century and early years of the 21st to explore new methods in vaccine development. These include recombinant expression of viral proteins with vaccine potential and in the 1980s the first recombinant viral vaccine was produced by expression of hepatitis B virus-like particles (VLPs) in yeast. More recently VLP vaccines of human papillomaviruses produced in yeast or in insect cells using recombinant baculovirus have been licensed.

Genetic manipulation has also been used to insert viral antigenic proteins into the genomes of non-pathogenic vector viruses such as vaccinia virus, adenoviruses and vesicular stomatitis virus (VSV). Recombinant adenovirus expressing the spike protein of the pandemic SARS-CoV-2 virus is being tested as a potential vaccine against COVID-19 and recombinant VSV expressing the envelope protein of ebola virus has recently been licensed for human use.

Drugs

Antiviral drug development has been slow and difficult and there are still relatively few viral disease for which effective drugs are available. A summary of some of the highlights of antiviral drug development are shown in [Table 4](#). The relative simplicity of viral

Table 4 Selected examples of anti-viral drug development

Year	Drug	Mode of action	Target virus
1957	interferon	Developed as a registered drug in 1980s and 1990s induces antiviral state in cells	HCV, HBV and others
1963	idoxuridine	First approved antiviral drug inhibits viral polymerase	HSV
1968	amantadine	Viral ion channel blocker	influenza
1972	ribavirin	Inhibits viral polymerase	HCV, RSV, etc.
1979	acyclovir	Inhibits viral polymerase	Herpes viruses
1987	zidovudine	Inhibits reverse transcriptase (RT)	HIV
1995	saquinavir	Viral protease inhibitor	HIV
1996	RSV-IGIV	Neutralizing antibodies	RSV
1996	nevirapine	Non-nucleoside RT inhibitor	HIV
1996	HAART	Combined drug formulations	HIV
1999	zanamivir/oseltamivir	Neuraminidase inhibitors	influenza
2011	telaprevir	Viral protease inhibitor	HCV
2014	lepidasvir	NS5A (protease) inhibitor	HCV
2013	sofosbuvir	NS5B (polymerase) inhibitor	HCV
2016	Combination DAA therapy	Triple combinations of direct acting antiviral drugs	HCV

genomes means that there are few virus specific targets for inhibitory compounds. The first drug to be licensed was amantidine in 1964, which inhibits influenza by blocking a viral ion channel. Amantidine suffered from a drawback common to many antiviral drugs in that resistant viruses arose by mutation very rapidly. The anti-herpes drug acyclovir, developed in 1971, was successful as the acquisition of resistance was rare.

The emergence of HIV in the early 1980s presented a new therapeutic challenge as the disease AIDS is progressive and incurable and vaccine development was (and still is) unsuccessful. A repurposed drug, AZT, effectively inhibited the viral reverse transcriptase and was useful until the selection of resistant variants of the virus abrogated its benefits. The problem of drug resistance was eventually addressed by the inclusion of other compounds, inhibitors of the viral protease for example. Acquisition of resistance simultaneously to multiple drugs is statistically rare and usually results in reduced viral fitness.

In 1989 the agent responsible for non-A-non-B hepatitis was identified by Houghton *et al.* This was the first virus to be discovered using molecular biology techniques and was termed hepatitis C virus (HCV). Interferon was first used to treat this chronic infection and was partially effective. Subsequently, intense drug discovery programmes involving many approaches, including structure-guided drug design methods, have culminated in current treatment regimens involving cocktails of drugs targeting different viral targets. This approach, as with HIV, overcomes the rapid selection of variants resistant to individual compounds and, in contrast to HIV, is curative in most cases.

Virus Emergence and Human Activities

The history of virology has been punctuated by eruptions of epidemic and pandemic diseases. These disturbances of virus/host equilibria arise as consequences of three main factors:

(1) Changes in the host conditions and environmental changes.

The evolution of human society and the global dominance of our species has impacted greatly on the interactions with pathogens, including viruses, with ourselves, our domestic animals and food crops. The change from a small group, hunter/gatherer lifestyle to static agricultural economy altered the density distribution of humans, crop plants and livestock alike. Clearly changes in the dynamics of pathogen/host interactions reflected these human driven changes. Expansion of the human population and increasing concentration in urban crowded conditions greatly increase the potential for pathogen spread. These factors almost certainly explain many of the devastating epidemics that have plagued humans since time immemorial. Striking recent examples of the effects of changes in animal husbandry and high density factory farming are outbreaks of “bird flu” that can kill thousands of birds over-night in high density chicken sheds.

Other examples of severe viral epidemics resulting from human activities are the depopulation of the Americas due to the introduction of disease such as smallpox, measles and influenza by European colonizers in the 15th and 16th centuries, decimation of the cattle populations (wild and domesticated) by rinderpest in the 1980s and control of European and Australian rabbit populations following the introduction of the myxomatosis virus from South America in the 1950s.

(2) Mutations of commonly occurring viruses with consequent major effects on virulence and transmission.

Not only do viruses replicate to produce vast numbers of progeny, many use error prone RNA dependent polymerases (e.g., picornaviruses, myxoviruses and retroviruses). As a consequence, virus populations typically comprise a complex mixture of variant mutant genomes referred to as quasi-species. Occasionally mutant viruses capable of exploring a new evolutionary avenue may be selected from the quasi-species pool to initiate a new disease phenotype. Influenza is a classic example of a virus that has caused frequent epidemics due to accumulation of mutations in its surface proteins sufficient to evade host

population immunity through antigenic drift and pandemics following genome segment exchange to produce antigenic shift. This occurred on several occasions throughout the history of virology and has been responsible for some of the most devastating pandemics of the past century; the most notorious being the 1918 “Spanish Flu” pandemic which affected all parts of the globe in a short space of time and is thought to have resulted in 50–100 million deaths.

A further example of a major change in host range associated with “minor” mutation occurred in the 1970s. A new and highly pathogenic disease appeared in domestic dogs and was transmitted across the globe in a short period of time. Sequencing of the “new” virus showed that it differed in just one or two amino acids in the structural protein region from feline parvovirus, it most likely appeared as a new and devastating disease in dogs as a consequence of a mutation which affected the host range of the virus.

(3) Transmission of viruses between species; emerging viruses.

The continual expansion of the human population and encroachment into formally underpopulated habitats has resulted in frequent epidemics and pandemics of “new” diseases via zoonotic inter-species transfer of viruses. Many of the most damaging viral epidemics and pandemics of human disease in the past century have arisen following the introduction of a novel virus originating from animal sources not commonly encountered by humans.

A well-documented example of zoonotic transfer is the so called “four corners” disease which appeared in the western United States in 1993 in a desert region where the states of Utah, Colorado, New Mexico and Arizona meet. Virologists from CDC were called in to investigate a new and highly pathogenic respiratory syndrome that appeared in the local communities. The causative agent was discovered to be a hantavirus (sin nombre virus) commonly found in a species of mouse, *Peromyscus maniculatus*, in which it causes persistent asymptomatic infections. Inhalation of dust contaminated by infected mouse feces and urine during cleaning procedures resulted in severe respiratory disease in humans. This is a typical example of a virus crossing from a wild species to infect humans as a result of unusual exposure, usually due to habitat encroachment.

Many emerging viruses are highly pathogenic, often causing hemorrhagic diseases, but lacking the ability to transmit between humans sufficiently well to initiate widespread epidemics or pandemics. However, there are a number of examples from the past century of zoonotic transfer of animal viruses which are both highly pathogenic and sufficiently transmissible between humans to initiate extensive epidemics and pandemics. Periodic pandemics of highly pathogenic influenza have been recorded and characterized in the past century, and contemporary accounts of devastating plagues in past centuries can be tentatively ascribed to influenza virus. The segmented structure of the influenza genome makes it especially well adapted to explore new host horizons via antigenic shift following dual infection of an intermediate host with viruses originating from different sources (e.g., bird and human). The outcome of such genetic exchange has been the evolution of new viruses including the genes allowing efficient growth in one host (e.g., human) combined with surface glycoproteins derived from another (e.g., bird). Several influenza pandemics have arisen during the past century and have been responsible for extremely high mortalities. The speed of global transmission of the 1918 “Spanish Flu” was facilitated by increased international travel together with disruption due to war.

In 1981 a new disease was observed in America. This was found to be caused by a new retrovirus, the lentivirus termed acquired human immunodeficiency or AIDS virus. From its early identification in the homosexual community of San Francisco, AIDS has gone on to become a major global pandemic, claiming the lives of an estimated 32 million people. Being a retrovirus, integration of the viral genome into the host cell chromosomes ensures that the infection is maintained lifelong. Despite the development of regimens that can control the disease, but require daily consumption of a cocktail of drugs, many millions of individuals are infected, especially in sub Saharan Africa. Sophisticated epidemiological studies have pointed to the origins of the AIDS epidemic being higher primates (chimpanzees and gorillas) in the tropical forests of central Africa. Transmission of AIDS into the human population almost certainly occurred by exposure through acquisition of bush meat.

Interspecies transfer of viruses with zoonotic potential is increasingly associated with human activities. An increase in live animal markets and in bush meat trade can result in increasing juxtaposition of species that would not make contact under natural conditions. These developments create ideal environments for exchange of infectious agents between species. Novel coronaviruses have emerged as significant human pathogens on three occasions since the beginning of the 21st century. In 2003 a new disease, Severe Acute Respiratory Syndrome or SARS, with a high case fatality rate appeared in China and was shown to be caused by a novel coronavirus. In the space of 6 months the virus was transported across the globe, emphasizing the important role of modern rapid international transport in the spread of infectious diseases, and resulted in 770 deaths. Fortunately, effective disease control measures, together with a limited innate ability of the virus to transmit within the population ensured the rapid elimination of the virus. Molecular epidemiological techniques showed that the causative agent of SARS was closely related to a virus isolated from civet cats in Chinese live animal markets and it is thought that these animals were an intermediate species enabling transmission to humans. SARS virus is also closely related to coronaviruses detected in certain bat species, which may be the primary source. It is becoming increasingly clear that bats are the source for many viruses that have the potential to spread into human (and other species) populations and cause serious disease. Bats seem to tolerate persistent infections, with little or no clinical symptoms, by viruses capable of causing serious disease in other species. The reasons for this are not understood and bats are being subjected to intense molecular, immunological and epidemiological studies to attempt to resolve the conundrum.

The second coronavirus to cause serious disease in humans is the MERS or Middle Eastern Respiratory Syndrome virus which was first identified in 2012. Camels appear to be the intermediate reservoir from which infections with this virus have been transmitted to humans although, again, bats are suspected as the original source. MERS is very pathogenic to humans but is not efficiently transmitted between individuals.

The third incursion of a novel coronavirus into the human population occurred at the end of 2019 and again may have originated from a live animal market in China. Sequence analyses suggest the possibility of the virus being acquired from pangolins or bats, both of which were sold in the market. This virus, termed SARS-CoV-2, causes severe, often fatal respiratory disease as was seen with the original SARS virus. However, in contrast to SARS-1, SARS-CoV-2 is transmitted very efficiently and transmission can occur before infected individuals experience symptoms. The combination of these properties has facilitated rapid spread of the virus globally, resulting in the most important pandemic disease since the Spanish Influenza more than a century ago. Within a few months of its appearance in the human population it has been responsible for hundreds of thousands of deaths and has stretched the health provisions of many countries to near breaking point. Attempts to control spread of the infection have resulted in the immobilization of one third of the global population and has caused havoc to economies worldwide. At the time of writing, this pandemic has still not reached its peak globally. Virologist and other infectious disease scientists have warned world governments for many years of the potential dangers from the introduction of emerging pandemic disease and the necessity for adequate preparation for such an event. Unfortunately, these warnings have gone largely unheeded.

Concluding Remarks

As can be seen from this brief historical introduction, the subject of virology has expanded enormously since its birth as a new scientific discipline a little over a century ago. It is now realised that viruses are by far the most numerous organisms on earth with the ability to influence the health and abundance of all cell-based living entities. They utilize the full range of molecular strategies imaginable to store and express their genetic information. They have proved to be invaluable probes to facilitate unraveling the basic molecular processes applicable to all cellular organisms. Investigation of their pathogenic mechanisms has revealed the enormous complexity of the essential anti-viral defense strategies adopted by all living organisms. The size and diversity of the global virome is expanding continuously as can be seen from the detailed articles comprising this Encyclopedia.

Introduction

Discussing the question of viruses origins requires first to specify the defining characteristics of viruses. For instance, if they are defined by their infectious genomes, then all infectious and parasitic mobile genetic elements (MGEs) can be considered to be viruses, even if they do not produce virions (capsidless viruses, *sensu* Koonin and Dolja), and the origin of viruses becomes equivalent to the origin of selfish infectious replicons. With this definition, one can argue that viruses originated at the very onset of life, since mathematical models suggest that genetic parasites probably emerged as soon as the first replicating systems were established. However, if viruses are defined by their specific mode of reproduction, i.e., the production of virions (viral particles) to disseminate their genomes, then the origin of viruses probably took place at a relatively late stage of life evolution, after the emergence of the ribosome, because even the simplest virion contains at least one protein. We will discuss here the problem of virus origins using this more restricted definition, as it allows us to make more reliable inferences based on what we know about modern viruses.

The Evolutionary Connection Between Viruses and Mobile Genetic Elements

Viruses are evolutionarily related to other MGEs, such as plasmids, transposons, and retrotransposons, sharing with them homologous replication proteins and proteins involved in relationships with their hosts (such as toxin-antitoxin systems in plasmids or other systems involved in the arm race between parasites and their hosts). As other MGEs, they are obligate parasites since they lack the ribosome, and are fully dependent of their cellular hosts for protein synthesis. However, they can be precisely distinguished from other MGEs by the fact that their genomes encode proteins involved in the formation of virions. For instance, the smallest virus, with two genes, and the smallest plasmid, with only one, only differ by the presence of a gene encoding a capsid protein in the viral genome.

Importantly, unlike other MGEs, viruses have the ability to profoundly modify the physiology of their hosts, transforming the infected cell into a machinery to produce virions, also called a virocell (as opposed to uninfected cells relying on their own ribosomes for protein synthesis, the ribocells). This process involves the reorganization of the cell metabolism and can sometimes lead to a symbiotic relationship with the host cell (a ribovirocell, with the virus genome integrated into that of its host) but also to the final destruction of the cellular structure, explaining why many viruses are pathogenic. Considering the virocell as a stage in the virus life cycle, along with a free-particles one, justifies considering viruses as *bona fide* organisms since they translate their genome and transcribe their genes into proteins that can be expressed with metabolic functions for instance. They have been proposedly defined as “capsid-encoding organisms” or “virion-producing organisms”, in order to emphasize the production of virions as the hallmark feature of viruses. The virocell concept (i.e., the cyclic nature of viruses, including as virocells) is not compatible with theories suggesting that viruses originated before cells (virus-first theories) since the virus itself is a cellular organism during one stage of its cycle, completely dependent on a pre-existing ribocell (a cell encoding ribosomes) for its formation. The origin of viruses hence becomes the origin of virocells, or more precisely, how some ribocells were first transformed into ribovirocells (i.e., started producing virions able to infect other ribocells) that finally became lethal for the infected cells, producing genuine virocells.

From the above considerations, the question of virus origins can be divided into three separate aspects: (1) the origin of capsidless parasitic MGEs, (2) the origin of capsid proteins and more generally of virions, (3) the mechanisms behind the association of parasitic MGEs and virions to produce *bona fide* viruses. Importantly, it is unclear if the answers to these questions would be the same for RNA and DNA viruses. Indeed, unlike ribosome-encoding organisms (Archaea, Bacteria, and Eukarya), viruses – and other MGEs – exhibit an astonishing diversity of genome chemistry, structure and arrangement. Here, we will separately address the question of the origin of RNA and DNA viruses, as well as the origin of viruses whose life cycle involves both RNA and DNA, although the typical reproduction mechanism of all these viruses suggests some common, recurrent themes to explain why the viral mode of reproduction was probably selected many times in the course of life evolution.

The Origin of RNA Viruses

It is often assumed that RNA viruses originated first since RNA should have antedated DNA as genetic material in early life evolution. Some authors have speculated that both RNA and DNA might have originated and co-existed in a prebiotic world, but it seems more likely that DNA originated from RNA at a cellular stage and that the modern cell metabolism recapitulated the historical pathway that led from RNA to DNA. DNA is indeed a modified form of RNA and the substrates of DNA synthesis, the

Fig. 1 Schematic hypothesis for the formation of the first RNA viruses in the RNA/protein world. An RNA ribocell (with ribosomes) contains here two linear chromosomes (in the gray area) with genes encoding replicase (black), a membrane fusion protein (blue) and RNA binding protein on different chromosomes. When these three genes are present on the same chromosome (with fusion of the latter two) the chromosome can be transferred by vesiculation from one cell to the other, becoming selfish elements. The vesicle carrying this chromosome (now a viral genome) become a virion whereas the infected cell become a virocell.

deoxynucleotides, are still produced in modern cells from the modification of the RNA substrates, ribonucleotides. It is thus very likely that the historical transition from RNA to DNA took place in *bona fide* cells with RNA genomes. The possible existence of such RNA cells has sometimes been denied because of the intrinsic instability of RNA and the short size of RNA virus genomes. However, RNA repair mechanisms as well as proof-reading endonucleases that can increase RNA replicase fidelity have been discovered, suggesting that ancient RNA cells possibly had RNA genomes longer than those of extant RNA viruses. Moreover, it is unclear if modern RNA viruses are good models to infer the ancient RNA cell physiology because small genomes and unfaithful replication can sometimes be advantageous for viruses. Notably, the RNA cells that gave rise to the first DNA cells probably already had elaborated ribosomes, since the RNA to DNA transition requires a complex cellular metabolism to produce in abundance both ribonucleotides and sophisticated proteins, such as ribonucleotide reductases, thymidylate synthases and reverse transcriptases. The first RNA viruses might have thus originated in such a world of RNA/protein cells from the combination of selfish RNA replicons with gene(s) encoding cellular proteins that facilitated the transfer of these replicons between RNA/protein cells (Fig. 1).

The Origin of Selfish RNA Replicons and Their Relationships With Modern RNA Viruses

In the ancient world of RNA cells, diverse types of selfish and non-selfish RNA replicons (circular or linear RNA plasmids, single or double-stranded) should have coexisted with probably important overlap between both. At some point in the history of life, after the emergence of proto-ribosomes, these RNA replicons started to be replicated by more and more sophisticated replicases (the ancestors of modern RNA-dependent RNA polymerases). It is likely that several different (non-homologous) types of RNA replicases, but also probably of RNA helicases, ligases, and nucleases, originated in the ancient world of RNA/protein cells. Different non-homologous families of these enzymes have indeed been described in the modern biosphere. These families are certainly very ancient since they can be divided into divergent subfamilies widespread in the current living world.

Remarkably, the RNA replicases of all known RNA viruses belong to a single protein superfamily that also includes reverse transcriptases encoded by reverse-transcribing viruses (RTV) and retroelements. RNA viruses and RTV have been therefore recently classified by the ICTV (International Committee on Taxonomy of Viruses) into the same realm, the *Riboviria*. It is tempting to conclude that replicases of *Riboviria* are the descendants of the RNA replicase that was used for replication in ancient RNA cells and that the first RNA viruses originated from a single class of selfish RNA replicons encoding this replicase. However, several other ancient families of RNA- or DNA-dependent RNA polymerases are present in the modern biosphere and could be the descendants of RNA replicases from extinct lineages of RNA cells and/or RNA viruses. This is the case of the monomeric RNA polymerase that is now used for transcription by some bacteriophages (thereafter called bacterioviruses), or else of an intriguing family of RNA/DNA

polymerases distantly related to the typical cellular RNA polymerases that perform transcription in the three domains of life (Archaea, Bacteria, and Eukarya). Some of these atypical and poorly known nucleotide polymerases use RNA as template and are involved in post-transcriptional gene silencing in eukaryotes, whereas others, such as the protein YonO encoded by a *Bacillus subtilis* prophage, function as transcriptase for some bacteriophages widespread in Bacteria.

It is likely that the transition from RNA to DNA-based cells has been a major bottleneck in cellular evolution. It is thus possible that many ancient RNA virus lineages did not survive this bottleneck and that *Riboviria* are the only lineage of ancient RNA viruses that survived the emerging DNA cells (the early *Riboviria* hypothesis). One can even imagine that all ancient RNA viruses disappeared and that *Riboviria* emerged later on during DNA cell evolution (the late *Riboviria* hypothesis).

The early *Riboviria* hypothesis is supported by their extreme diversity and the relative simplicity of most of them. *Riboviria* replicases are extremely divergent between the different subgroups in that realm. *Riboviria* also differ in terms of capsid components, genome structure (single of double-stranded RNA, segmented or not) and transcription/replication mechanisms (positive or negative single-stranded RNA viruses). Moreover, all *Riboviria* have rather small genomes and some of them have very simple life cycle, suggesting that they could correspond to “primitive” viruses, resembling the first RNA viruses that emerged on our planet. In this line of thought, it has been suggested that positive-sense RNA viruses, in which the same molecule functions as both a genome and mRNA, correspond to the most ancient ones.

A Scenario for the Origin of *Riboviria*

Most positive-sense RNA viruses have icosahedral virions with capsid proteins characterized by a simple structural fold called the “single jelly roll” (SJR). The protein domains containing this fold are often linked to another largely unstructured, positively charged N-terminal domain, allowing the packaging of the RNA in the capsid shell. Many cellular proteins widespread in the three domains of life also contain the SJR fold, suggesting that SJR proteins were already diversified at the time of LUCA. These proteins were thus probably already present in the world of RNA/proteins cells. Interestingly, many SJR proteins have carbohydrate recognition properties. As stated by Krupovic and Koonin, “a protein with such a property would be immediately beneficial to the virus because, in addition to providing a protective shell for the genome, it could ensure specific binding of the viral particle to the host cell”. One can thus imagine a rather simple scenario in which the first *Riboviria* originated from the recruitment by a selfish RNA replicon of a gene encoding such SJR protein linked to an RNA binding domain, the carbohydrate recognition properties of the SJR domain allowing the first virions to interact with glycoprotein receptors at the surface of RNA cells (Fig. 1).

The historical validity of this scenario can a priori be tested by the phylogenetic analysis of the RNA replicases combined to an analysis of the SJR capsid type distribution among *Riboviria*. Although sequences of viral RNA replicases are difficult to align, a whole tree of the *Riboviria* realm based on viral RNA replicases (rooted using reverse transcriptases of retroelements) has been published in 2018 by Koonin *et al.* (schematized in Fig. 2(A)). Based on this phylogeny, the authors suggested that *Riboviria* originated indeed from a single ancestor with the SJR capsid protein (thereafter called the SJR ancestral hypothesis). However, several groups of *Riboviria* produce capsid proteins with folds unrelated to the SJR. This is the case in particular of *Leviviridae* that infect Bacteria, negative-sense RNA viruses and for most double-stranded RNA viruses. The authors of the SJR ancestral hypothesis suggested that the SJR capsid protein was replaced several times independently by new types of capsid proteins during the diversification of *Riboviria* lineages.

The rooting proposed by Koonin *et al.* (using reverse transcriptases as an outgroup) does not really support the SJR ancestral hypothesis though because it implies that *Riboviria* with the SJR fold were originally present in only one of the two main branches of the replicase tree (Fig. 2(A), with the SJR of *Coronaviridae* being a secondary acquisition). One can thus imagine that *Leviviridae* (at the origin of one of the two major branches) have emerged independently from other *Riboviria* via the recruitment of different capsid proteins by replicons sharing the same type of replicase. However, if reverse transcriptases originated from RNA replicases, as in the early *Riboviria* scenario, the tree could instead be rooted within the diversity of replicases from positive-sense RNA viruses (Fig. 2(B)). In that case, positive-sense RNA viruses with an SJR capsid are present in the two main branches of the tree, making the ancestral SJR hypothesis a reasonable possibility (Fig. 1).

In any case, it remains to be understood how the first virions acquired the ability to egress from the cell and to infect another cell. Modern *Riboviria* are not good models to infer such events since they have co-evolved for billions of years with their DNA-based cell hosts and became adapted to their cellular fabric. For instance, *Riboviria* infecting eukaryotes have learnt how to manipulate the eukaryotic vesicle trafficking system for delivery and egress (often via the endosomal pathway) and for building viral factories. Similarly, *Riboviria* infecting bacteria are now dependent on complex and rather recent bacterial appendages (F pili in the case of *Leviviridae* and type IV pili in the case of *Cystoviridae*) that were most likely absent in ancient RNA cells. At first sight, eukaryotic *Riboviria* represent a simpler model since they do not have to cross several membranes. However, in the simplest modern *Riboviria* infecting eukaryotes, both egress and exit are completely dependent on the elaborated endosomal pathway of eukaryotic cells and many of them need to manipulate the endoplasmic reticulum or other elaborated eukaryotic structures to build their viral factories. A *minima*, one should imagine that the first cell in which a proto-virion became a virion already had the ability to excrete and to integrate such large macromolecular structure.

It has been suggested that extracellular membrane vesicles (EVs) that are produced by most modern cells could be interesting models to understand the origin of viruses because of the similarities between these vesicles and virions. However, the mechanisms of excretion and fusion of EVs in the three domains of life still remain poorly known. The best documented mechanisms are those occurring in eukaryotes and they are exceedingly complex with again the involvement of the endosomal

Fig. 2 Schematic history of the *Riboviria* realm based on the phylogenetic analysis of their RNA replicase. RNA viruses or Reverse Transcribing Viruses (RTV) infecting eukaryotes in red and RNA viruses or RTV infecting bacteria in green. The names of viral families infecting Bacteria are in green, the name of viral rank containing only viruses infecting eukaryotes are in red. The phylogeny is based on those published by Wolf *et al.* in 2017. In this publication, the authors proposed to root the tree between replicases of RNA viruses and reverse transcriptase (A). They propose a scenario in which RNA viruses infecting eukaryotes emerged from RNA viruses and/or retroelements infecting prokaryotes (green circle). Alternatively, if reverse transcriptases originated from RNA replicases, the tree can be rooted within replicases of RNA viruses (one possible such rooting, between the major groups of positive sense RNA viruses, is proposed in B). In that case, RNA viruses infecting eukaryotes might derived from ancient RNA viruses that overlapped with the ancient world of protein/RNA cells (pink circle). SJR: members of the respective clade contain viruses with SJR fold in their capsid protein. SJR in faint orange box, secondary capture of the SJR fold (see text). + positive sense RNA viruses, – negative sense RNA viruses, ds: double-stranded RNA viruses.

pathway. In order to imagine evolutionary scenarios for a vesicle-based origin of virions, one should look at simpler types of vesicles. This might be possible, and it is often assumed that ancient cells that predated LUCA already produced vesicles. Interestingly, lipid vesicles are rather easily formed in prebiotic conditions and it has been shown that addition of simple peptides can trigger vesicles fusion. One can thus imagine that some of the first proteins synthesized by proto-ribosomes (long after the origin of the first RNA-based cells) have triggered vesicle production by inducing membrane curvature, whereas other proteins made possible vesicle fusion. These proteins might have been recruited later on in the formation of early virions (Fig. 1). In modern cells, EVs can transfer RNA or DNA from cells to cells (vesiculation), including plasmids (plasmidion) and viral genomes (viral vesicle). This process might have been at the origin of virion dissemination and infectivity.

The Origin of RNA Viruses Infecting Eukaryotes

A major conundrum in the hypothesis that *Riboviria* derived from ancestral RNA viruses from the RNA-cell world is that *Riboviria* are very abundant and diverse in Eukaryotes, but very rare in Bacteria and completely unknown in Archaea (Fig. 3(C)). Bacterial RNA viruses only correspond to two families, *Leviviridae* and *Cystoviridae*, out of the 70 presently described *Riboviria* families, and they are only known to infect a few bacterial lineages. In the *Riboviria* early hypothesis, if *Riboviria* were present at the time of LUCA, one should imagine that they were later on entirely lost in the stem branches of the archaeal domain and that most of them also disappeared in the stem branch of the bacterial domain (Fig. 3(A), *Riboviria* in red). It has been suggested that RNA viruses are absent in Archaea because the last archaeal common ancestor (LACA) was a hyperthermophile. The reasoning is that RNA is much more fragile than DNA at high temperature. By the same token, most RNA viruses might have been lost in Bacteria if the last bacterial common ancestor (LBCA) also lived at high temperature. In support of this hypothesis, reconstructions of ancestral RNA and universal protein sequences by Manolo Gouy *et al.* have suggested that both the LACA and the LBCA were thermophilic or hyperthermophilic organisms. In the case of Bacteria, it is also possible that emergence of the peptidoglycan in the stem branch leading to Bacteria prevented most ancient viral lineages, especially those of RNA viruses, to survive in this lineage. In contrast, it has been suggested that RNA viruses were successful in eukaryotes because they could efficiently replicate in the intracellular membrane-rich cytoplasm of their cells. *Riboviria* indeed often use the endoplasmic reticulum membrane of eukaryotic cells to build their viral factories.

Fig. 3 The mysterious origin of *Riboviria* infecting eukaryotes. (A) Early *Riboviria* hypothesis. In this scenario, based on the Woese's tree of life (the three domains model) *Riboviria* already present at the time of LUCA (black circle). They completely disappeared in the stem branch leading to Archaea during a period of adaptation to very high temperature (pink box). They partly disappeared in the stem branch leading to Bacteria during a period of adaptation to high temperature (light pink box). (B) the late *Riboviria* hypothesis. In this scenario, based on the eocyte tree of life (the two domains model), Eukarya are a subgroup of Archaea. *Riboviria* were present or not at the time of LUCA. If they were present, they later on disappeared in the stem branch leading to Archaea. If they were not present, they appeared (purple capsids) in the stem branch leading to Bacteria and/or eukaryotes. If they appeared in Bacteria (the bacterial ancestor scenario), some subgroups of *Riboviria* were transferred later to the ancestor of eukaryotes via bacterial endosymbionts such as the mitochondrial ancestor. (C) schematic distribution of RNA and DNA viruses in the three domains of life. Adapted from Nasir *et al.* (2014).

The alternative hypothesis to explain the abundance of *Riboviria* in eukaryotes is that modern RNA viruses did not originate from ancient ones that predated LUCA but either from bacterial *Riboviria* (the bacterial ancestor scenario) or *de novo* in the proto-eukaryotic stem lineage (Fig. 3(B), *Riboviria* in red and purple for the early and late scenarios, respectively). These two late eukaryotic *Riboviria* hypotheses are not contradictory and can each be valid for different viral families. In the bacterial ancestor scenario, one should imagine that eukaryotic *Riboviria* originated from *Riboviria* that infected bacteria co-evolving with proto-eukaryotes (dotted line in Fig. 3(B)). For instance, it has been suggested that the ancestors of eukaryotic *Riboviria* might have originated from *Riboviria* that infected the bacterium at the origin of mitochondria. In that scenario, it is however unclear how these RNA viruses “learned” to infect the proto-eukaryote (or the archaeon) that engulfed their bacterial host, especially considering that eukaryotes and bacteria have completely different transcription and translation machineries. Moreover, the RNA replicases of eukaryotic *Riboviria* did not emerge from within those of bacterial RNA viruses in phylogenetic analyzes, except if one assumes that RNA replicases originated from bacterial reverse transcriptases (Fig. 2(A)). On the contrary, the replicases of bacterial *Cystoviridae* and *Leviviridae* (in green in Fig. 2) branch within those of eukaryotic RNA viruses if the tree is rooted within positive-sense viruses with SJR-type capsids (Fig. 2(B)). The second scenario, in which modern eukaryotic RNA viruses originated *de novo* in the proto-eukaryotic stem lineage, should be reconciled with the fact that the replicases of *Riboviria* infecting bacteriophages and eukaryoviruses are homologs. One should imagine in that case that these viruses emerged independently from the recruitment of different capsid proteins by selfish RNA MGEs encoding homologous replicases. It seems however difficult at the moment to imagine that the present diversity of *Riboviria* in eukaryotes could have entirely emerged from the limited number and diversity of *Riboviria* known in Bacteria (even if this diversity is probably largely underestimated).

The Origin of Reverse-Transcribing RNA and DNA Viruses

The genomes of some *Riboviria* is retrotranscribed into DNA in the virocell and new RNA genomes are produced from this DNA template. In a symmetric way, the genome of some DNA viruses (e.g., *Hepadnaviridae* and *Caulimoviridae* families) is retrotranscribed into RNA and new DNA genomes are produced from this RNA template. These fascinating Reverse Transcribed Viruses (RTV) have

been grouped under the *Revtraviricetes* class (*Paramavirae* kingdom), within the *Riboviria* realm with RNA viruses. Most RTV have RNA genomes and belong to the *Ortervirales* order, whose name has been derived from the reverse of retro. *Ortervirales* are divided into several families including the well-known retroviruses that share similar capsid and nucleocapsid proteins/domains and a family. Notably, RTV viruses of the *Hepadnaviridae* family encode a capsid protein which is unrelated to those of viruses of the *Ortervirales*.

The critical step in the life cycle of all these viruses is the reverse-transcription of RNA into DNA by reverse transcriptases. Since a reverse transcriptase activity was necessarily involved in the transition from RNA to DNA genomes, it is tempting to suggest that the origin of DNA coincided with the emergence of the first RTV, in agreement with the idea that DNA emerged in the viral world. The “out of virus” hypothesis for the origin of DNA posits that an RNA virus modified the chemistry of its genome as a protective feature against the defense mechanisms of their hosts that targeted RNA genomes. This might have taken place in two steps with first the emergence of viruses with U-DNA genome (following the emergence or recruitment of a ribonucleotide reductase activity) and finally with T-DNA genomes (following the emergence or recruitment of a thymidylate synthase activity). If this scenario has taken place in an ancient lineage of RNA viruses that became an RTV with an RNA genome, and later on an RTV with a DNA genome, one has to understand what could have been the direct selection pressure favoring the presence of a DNA intermediate in the virocell. This DNA intermediate might have been a storage form allowing the viral genome to persist in an inhospitable environment for foreign RNA. It remains to be understood how RNA cells used to discriminate between an invader RNA and their own RNA genome.

Although both RNA and DNA RTV are evolutionarily related and have been grouped in the same class, *Revtraviricetes*, it is unclear if the RT that participated to the RNA to DNA transition was a direct ancestor of the RT of *Revtraviricetes*. Modern RT are very diverse and can be divided in several phylogenetic clades, those encoded by *Revtraviricetes* belonging to only one of them, all the others corresponding to RT encoded by retroelements widespread in Eukarya and rare in Bacteria. Notably, unlike retroelements, RTV are only present in eukaryotes, their broad distribution within eukaryotes suggesting ancient origin(s), possibly prior to the emergence of eukaryotes. One can again propose either that RTV have been lost in Archaea and Bacteria or that they have originated in the eukaryotic stem lineage. In any case, *Revtraviricetes* should have coevolved with the eukaryotic lineage for a very long time and became adapted to these complex hosts, possibly recruiting new types of capsids.

The RT of *Revtraviricetes* might still be the direct descendants of those that promoted the RNA to DNA transition, but this transition might have been promoted instead by an RT more closely related to the RT of some clades of modern retroelements or from an extinct, or not yet discovered lineage of RTV or retroelement. One can even imagine that the reverse transcriptase that promoted the RNA to DNA transition was not encoded by a *Revtraviricetes* ancestor, not even by another group of *Riboviria*, but by a virus from an extinct lineage.

The Origin of DNA Viruses

Whereas DNA viruses are less abundant than RNA viruses in eukaryotes, they are largely dominant in the bacterial biosphere and every known archaeal virus has a DNA genome. It has been suggested that DNA viruses are less abundant in eukaryotes because the emergence of the nucleus prevented DNA viruses to have an easy access to the DNA replication apparatus of proto-eukaryotes, whereas RNA viruses do not need such access. As a consequence, many ancestral lineages of DNA viruses were eliminated before the time of the last eukaryotic common ancestor (LECA) and only a few DNA viruses finally developed the tricks to replicate within the nucleus. Indeed, many DNA viruses infecting eukaryotes have rather large genomes, encode their own replication apparatus and replicate within cytoplasmic viral factories. However, Bacteria and Archaea are also infected by some DNA viruses with large genomes and autonomous replication machineries, indicating that such viruses are very ancient and predated the origin of the nucleus. Most DNA viruses have double-stranded DNA genomes (dsDNA) (circular or linear) although many DNA viruses infecting eukaryotes and a few of those infecting archaea and bacteria have single-stranded DNA genomes (ssDNA) (circular or linear). Viral dsDNA genomes exhibit a surprising size variability with lengths varying from 1.7 kb (two genes) for circovirus up to 2.5 Mb (more than two thousand genes) for pandoravirus, both infecting eukaryotes. These genomes are replicated by an amazing diversity of DNA replication mechanisms and machineries.

If ancient RNA genomes were progressively transformed into DNA genomes during the RNA to DNA transition, one should imagine that ancient RNA replicators were transformed into DNA replicators and that enzymes previously used to replicate and manipulate RNA were progressively recruited by evolving DNA replicators to manipulate DNA. This is exemplified by the fact that many enzymes involved in RNA or DNA metabolism, such as nucleotide polymerases, nucleases, or helicases are homologous. Some viral enzymes involved in DNA genome replication are homologous to their analogs in cellular organisms but others are specific to both RNA and DNA viruses, as in the case of superfamily III helicases. As a rule, there are usually several families of non-homologous enzymes for each activity (exemplified by the case of RNA and DNA polymerases) suggesting a complex and ancient history of these enzymes that probably overlapped with the RNA to DNA transition. DNA replicators that emerged during the RNA to DNA transition might have later on recruited capsids from RNA viruses or ancient cellular proteins to produce various types of DNA viruses. This evolutionary trajectory has been demonstrated in the case of several families of small ssDNA viruses that infect eukaryotes and have been grouped into the *Cressdnaviricota* phylum. These viruses originated several times independently from different rolling-circle DNA plasmids that recruited their SJR capsid proteins from *Riboviria*. In that case, the diversification of *Riboviria* indeed preceded the emergence of *Cressdnaviricota*. A similar scenario might have taken place earlier for other lineages of

DNA viruses, but it is also possible that DNA viruses originated from the recruitment by DNA plasmids for their capsids of novel types of proteins that were not previously used as capsid proteins by RNA viruses. For instance, members of the order *Ortervirales* are evolutionarily related to viruses of the *Hepadnaviridae* family because they share homologous reverse transcriptase, but they have unrelated capsid proteins.

An open question is the timing of DNA virus emergence: did they originate before or after the LUCA? This question is related to another one, i.e., did LUCA already had a DNA genome or still an RNA genome? Most biologists consider that LUCA already had a DNA genome since all current cellular organisms have DNA genomes. However, in that case, one would have expected the DNA replication proteins in the three domains to be homologous, which is not the case. The RNA LUCA hypothesis is actually supported by the fact that the three major proteins involved in DNA replication in Archaea/Eukarya and in Bacteria (the replicase, the primase, and the helicase) are not homologous. To explain this paradox, it has been suggested by proponents of the DNA LUCA that the replication proteins present in LUCA were the ancestors of the modern archaeal ones and that they were replaced in the bacterial branch by the ancestors of the modern bacterial ones, possibly of viral origin. On the other hand, the proponents of an RNA LUCA argue that LUCA was probably simpler than modern organisms, with smaller ribosomes and a less specific transcription initiation system, suggesting an early stage – possibly still RNA based – in cellular evolution.

The transition from RNA to DNA genomes post-LUCA would also explain why the tempo of protein evolution was drastically reduced during the transition from LUCA to the last common ancestor of the three domains. If LUCA still had an RNA genome, it is possible that DNA viruses originated independently and diversified during this transition in the stem lineages of the three modern domains. In agreement with this hypothesis, many families of DNA viruses are indeed unique to a particular domain. This is especially the case for those infecting cells of the *Archaea* domain and that exhibit a great variety of capsid proteins completely unrelated to those of bacteriophages and eukaryoviruses.

However, there are two exceptions to this observation, corresponding to the so-called cosmopolitan viruses. The latter belong to two realms that include viruses infecting cells from the three cellular domains, *Varidnaviria* (formerly known as the PDR1/Adenovirus lineage) and the *Duplodnaviria* (formerly the HK97 lineage). *Varidnaviria* are characterized by homologous major capsid proteins containing a DJR fold oriented vertically with respect to the capsid surface and a packaging ATPase of the FtsK/HerA superfamily P-loop ATPases family, whereas *Duplodnaviria* (*Duplodna* standing for double-stranded DNA) grouping *Herpesviridae* infecting animals and head-tailed viruses infecting Archaea and Bacteria (*Caudovirales*) are characterized by homologous major capsid proteins containing the so-called HK97 fold and packaging ATPases called Terminases. It has been assumed from their universality that ancestors of these cosmopolitan DNA viruses were already thriving at the time of LUCA. However, in that case, one would have expected their evolutionary history to be congruent with those of cellular organisms in which Archaea and Eukarya are closely related and very divergent from Bacteria in terms of molecular biology and universal protein sequences. This is not the case. On the contrary, *Varidnaviria* and *Duplodnaviria* infecting bacteria are much more similar to those infecting Archaea than to those infecting eukaryotes. For instance, among *Duplodnaviria*, head and tailed viruses infecting Archaea and Bacteria are so similar in terms of virion structure and gene content that they have been classified into the same order, *Caudovirales*. These viruses are extremely divergent from *Herpesviridae*, only sharing with them very distant pATPase, MCP and several other proteins. The same situation is observed in the case of *Varidnaviria*: bacteriophages and archaeoviruses of this realm are mixed in phylogenies based on their capsid protein and packaging ATPases and have been classified into the same class: the *Tectiliviricetes*. They form a group rather distant from the eukaryoviruses of this realm, *Nucleocytoviricota* and their viruses of the *Lavidaviridae* family (virophage) and Polintoviruses. Presently, *Adenoviridae*, which infect eukaryotes, have been classified with *Tectiliviricetes* by the ICTV, even though the structural analysis of their capsid protein suggested that they could be more related to those of other *Varidnaviria* eukaryoviruses.

Phylogenetic analysis of *Varidnaviria* and *Duplodnaviria* based on the concatenation of their major capsid proteins and packaging ATPases have produced trees in which archaeoviruses and bacteriophages are mixed and grouped together apart from eukaryoviruses (Fig. 4 for *Varidnaviria*). Such trees, which are not congruent with the cellular tree of life, suggests that some transfers of viruses have taken place between Archaea and Bacteria, or possibly between proto-archaea and proto-bacteria. An early transfer of *Caudovirales* from Bacteria to Archaea would explain why these viruses are more diverse and widespread in Bacteria than in Archaea.

Several scenarios can be proposed for the evolution of cosmopolitan viruses. They are illustrated in Fig. 4 in the case of *Varidnaviria*. Considering the huge diversity and distribution of *Varidnaviria* in Eukaryotes, one cannot exclude that these viruses originated in proto-eukaryotes and were later on transferred to Archaea and Bacteria (Fig. 4(A)). However, a published hypothesis suggests instead that they originated in Bacteria and were transferred to eukaryotes, possibly via mitochondria, as in the case of one of the two *Riboviria* late hypotheses (Fig. 4(B)). Finally, if the ancestors of *Varidnaviria* were already present at the time of LUCA, one should imagine that they were later on lost in Archaea and recovered from Bacteria (Fig. 4(C)). Similar scenarios can be proposed for *Duplodnaviria*. It is presently unclear if it will be possible in the future to choose between these different scenarios. One can hope that the discovery of new cellular and viral lineages in some isolated corner of our planet through the systematic and exhaustive screening of all environments will bring new insights in that matter, but this is far from a certitude.

An intriguing observation is that whereas viruses belonging to *Varidnaviria* and *Duplodnaviria* produce non-homologous virions and use non homologous packaging ATPase, they sometimes share homologous DNA replication proteins. In particular, some replication proteins used by *Caudovirales* infecting bacteria are related to replication proteins of *Nucleocytoviricota* (formerly known as the NucleoCytoplasmic Large DNA Viruses), the phylum of *Varidnaviria* eukaryovirus that includes giant viruses such as *Mimiviridae*. This suggests that various lineages of DNA viruses recruited homologous replication proteins that emerged in the world of viral and mobile elements during the transition from the RNA to the DNA world.

Fig. 4 The history of the realm *Varidnaviria*. A-C: Schematic history of the realm *Varidnaviria* with various rooting. This phylogeny is based on the phylogenetic analysis of their major capsid proteins and packaging ATPases (concatenation) published by Woo and colleagues in 2019: (A) the eukaryotic ancestor scenario, *Varidnaviria* originally infected proto-eukaryotes (pink oval) and were later transferred independently to Archaea and Bacteria. (B) the bacterial ancestor scenario, *Varidnaviria* originally infected proto-bacteria and were later transferred to proto-bacteria (pink oval). (C) the LUCA scenario, *Varidnaviria* were present at the time of LUCA (black circle) and later on lost in early proto-Archaea. There were later introduced in proto-Archaea from proto-bacteria (green oval). (D) the three domains universal tree of life. Whereas Archaea are mixed with Bacteria in the "viral tree" (A, B, C) they are sister group to Eukaryotes in the three domains tree and they are the ancestors of eukaryotes in the eocyte tree (Fig. 3(B)). E, zoom on the phylum *Nucleocytoviricota* phylogeny (rooted with Polintoviruses) based on those published by Guglielmini *et al.* in 2019, giant viruses are in purple.

The Origin of Giant Viruses and Megaphages

Some members of the *Varidnaviria* and *Duplodnaviria* realms have large genomes and virion size. These "giant viruses" (*Mimiviridae*, pandoraviruses, Orpheovirus) or "megaphages" (*Caudovirales*) encode from several hundred up to two thousand genes, and some of them produce virions that can be seen by optical microscopy. The discovery of these viruses has rejuvenated the idea that viruses (at least some of them) possibly derived from ancient cellular lineages of obligate parasites that lost their ribosomes. This hypothesis is not supported by phylogenetic analyzes showing that giant viruses are scattered within their respective phyla and originated several times independently from smaller viruses (see Fig. 4(E) for the distribution of giant viruses – in purple – among *Nucleocytoviricota*). Their genomes most likely increased by gene recruitment and duplication, but also probably via extensive *de novo* gene production.

The "cellular origin" hypothesis has been proposed by some authors to explain the presence in the genome of giant viruses of a majority of genes without cellular homologs, supposedly derived from their ancient cellular ancestors. This was based on the traditional view that considers viruses as inert particles and mostly pick-pockets of cellular genes. However, during the virocell stage, one can anticipate that the well-known processes that trigger the formation of proto-genes and finally new genes from non-coding sequences in cellular genomes similarly take place in viral genomes during their replication. In fact, in all viruses, from the smallest to the largest, the majority of viral genes (called orfans) have no cellular homologs, testifying for the abundance of genes that directly originated in viral genome and were never transferred to their hosts. This is probably due to the high level of genome replication that occurs during the virocell stage of the virus life cycle. The same observation also holds for capsidless mobile genetic elements that also encode mostly "orfan" genes and that are likely another continuous source of new genes in the biosphere.

Some authors have favored the "cellular origin" hypothesis to explain the presence in the overall viral proteome of many proteins that share folds present in proteins from the three domains of life. This observation indeed strongly supports the idea that

viruses were already around at the time of LUCA but do not specifically support the cellular hypothesis scenario. It indicates that ancient viruses of that time would have indeed recruited ancient proteins carrying these folds but, conversely, it is also likely that cellular lineages thriving at the time of LUCA had already integrated in their genomes many genes originally produced in the world of viruses and other mobile genetic elements.

Conclusion

Our ideas about the place of viruses in the history of life have been improved these last decades with our better knowledge of the virus world and the identification of evolutionary relationships between major viral lineages. We have now a rather extensive view of most modern viral lineages. A high number of different types of capsid protein has been determined, confirming that viruses are polyphyletic if viruses' origin is assimilated to the acquisition by selfish replicons of protein(s) suitable for the production of infectious virions. Of the three classical scenarios for the origin of viruses, i.e., the virus first hypothesis, the regression hypothesis (cellular origin), and the escape hypothesis, only the latter has survived but in a rather different setting. Viruses did not originate from some chromosomal portions that escaped from their host genomes after the separation of prokaryotes and eukaryotes, as was still assumed not so long ago, but from selfish replicons that escaped from their hosts by inventing a new way of reproduction, the production of virion. For that purpose, selfish replicons were combined with gene cassettes encoding capsid proteins and other proteins involved in virion production (the chimeric hypothesis). These events took probably place very early in RNA-based cells to produce the first RNA viruses (the ancient escape hypothesis) and more recently to produce DNA viruses through the combination of selfish DNA replicons with new types of virions or virions recruited from RNA viruses. These events have taken place repeatedly and at different times in the history of life.

Many questions remain to be solved. It remains unclear if some modern viruses are the direct descendants of the first virus lineages or if the most ancient viral lineages have all vanished in the mists of time. In particular, we would like to know if reverse transcribing viruses are the direct descendants of those that participated to the historical RNA to DNA transition. The origin of eukaryoviruses with no clear-cut relatives in the two other domains also remains a mystery. Why archaeoviruses and eukaryoviruses are so different whereas the molecular biology of their hosts is rather similar (at least the basic processes)? Why RNA viruses are so abundant in eukaryotes and so scarce in Bacteria? How to reconcile what we know about virus history with the topology of the universal tree of life? Answering these questions will require at least to be clear on the position of eukaryotes in this tree, either as sister group to archaea in the so-called 3D model or deeply anchored within Archaea in the so-called 2D model, a question which is still in debate. A major advance in any case is that viruses are now recognized by more and more evolutionists as both part of the problem and of the answer. They are no longer viewed as byproduct of life's evolution but as major components that have strongly influenced the history of life on our planet.

The Virocell Concept

Patrick Forterre, Archeology Virology Unit, Institut Pasteur, Paris, France and French National Center for Scientific Research, Institute of Integrative Biology of the Cell, University of Paris-Saclay, Gif sur Yvette Cedex, France

The Virion/Virus Paradigm

The virocell concept has been proposed to counterbalance the traditional view which assimilates viruses to their virion (viral particles), the so-called “virus/virion paradigm” (sensu Forterre). From the time of their discovery, viruses were indeed assimilated to the infectious component capable of passing through filters used to retain bacteria. Later on, this infectious component turned out to be the viral particle – the virion – which became assimilated to the virus. The virus/virion paradigm became dominant among biologists because pictures of virions can be easily used to illustrate “what is a virus”, both for scientists and for the general public. This is obvious in the media but also in the scientific literature. The fight against viruses through vaccination also entrenched this way of thinking, since antibodies designed to prevent virus infection usually recognized components of the virion. In recent years, the virus/virion paradigm was also strengthened by the progress in the field of structural virology, when the virion structures could be determined at the molecular and atomic levels. Finally, a universal component of virions, the major capsid proteins, is now used to define viral lineages. The major capsid protein is often considered as the hallmark of the virus, because it is sometimes the only marker than can help discriminating between viruses and plasmids.

In agreement with the virus/virion paradigm, viruses were classified using both the shape of the virion (e.g., order *Caudovirales* groups all “head and tailed viruses”) and the nature of the nucleic acid present in the virion (RNA or DNA, single-stranded or double stranded, positive- or negative-sense RNA). In a few cases, the nucleic acid itself was assimilated to the virion, thus to the virus. Hence, naked infectious RNA molecules derived from *bona fide* RNA viruses were called capsidless viruses by Eugene Koonin and Valerian Dolja and officially recognized as viruses by the ICTV (International Committee for the Taxonomy of Viruses) (e.g., narnaviruses, endornaviruses, hypoviruses, etc.). The virus/virion paradigm is also reflected in most virus definitions. For instance, Jacob and Wolmann defined viruses as “a genetic element enclosed in a protein coat”, whereas Didier Raoult and Patrick Forterre, in a paper proposing a new definition of viruses, still describe a virus as “a capsid encoding organism that is composed of proteins and nucleic acids, self-assembled in a nucleocapsid”. The virus/virion paradigm also explains why André Lwoff includes the presence of a single type of nucleic acid (RNA or DNA) among criteria distinguishing viruses from cells. However, this is disputable since DNA viruses produce viral messenger RNAs that belongs to the virus. Accordingly, the Lwoff criteria is only valid if the virus is assimilated to the virion.

The virus/virion paradigm had several important consequences in the way most scientists consider viruses. This explains why they are often described as giant macromolecular entities – much like the ribosome – instead of living organisms. This is considered as a testament of an absolute gap between the cellular and the viral worlds. Viruses were thus expelled from the living realm by many biologists, including some leading virologists, as inert particles lacking the main attributes of life such as the production of energy and a self-sustaining metabolism.

Critics of the Virion/Virus Paradigm

The virus/virion paradigm was first criticized by Claudiu Bandea who wrote in 1983 that “the living phase of the virus is the vegetative phase when the virus shows the major physiological properties of organisms: metabolism, growth, reproduction”. The intracellular stage of the viral reproductive cycle can be indeed viewed as the most important aspect of this cycle because the virus expresses and replicates its genome during this stage. However, in line with the virus/virion paradigm, this stage is usually called the “eclipse phase” in the literature, being simply defined by the absence of visible virions. A major criticism of the virus/virion paradigm was made by Jean-Michel Claverie, following the discovery in 2003 of the giant Mimivirus and of its huge virus factories located in the cytoplasm of the infected amoeba. Jean-Michel Claverie states in 2006 that the virus/virion paradigm is a case of “when the finger points to the star, the fool looks at the finger” or else that “Interpreting the virion particle as ‘the virus’, is very much like looking at a spermatozoid and calling it a human”. He proposes that: “the virus factory should be considered the actual virus organism”. A weakness of this proposal was that, in contrast to viruses infecting eukaryotes (eukaryoviruses), viruses infecting archaea (archaeoviruses) or bacteria (bacteriophages) do not produce easily discernible virus factories. To extend the idea to the whole viral realm, Patrick Forterre and David Prangishvili combined the definition of Jean-Michel Claverie (the virus is the viral factory) with an old quote of André Lwoff: “the virus transforms the cell into a virus factory” and concluded that the infected cell is the real viral organism. The term virocell, i.e., “a virus expressing itself in a cellular form” was then proposed to illustrate this point (Fig. 1).

The virocells was defined as cells producing infectious virions that have the potential to produce new virocells, as opposed to ribocells, defined as cells containing ribosomes and dividing by binary fission. The notion of virocell is easy to understand when the genome of the infected cell is completely destroyed or inactivated because the infected cell remains obviously a cell, but without “cellular DNA” that could define it as a bacterium, an archaeon or a eukaryote. It became a virocell containing only viral genome.

Fig. 1 The various forms of the virus, virion, virocell and ribovirocell.

The virocell concept fits the definition of viruses as “*capsid encoding organisms*” or virion producing organisms, since the viral infection transforms the cell into a novel type of organism, a virocell. In the virocell, the cellular metabolism network is very often entirely re-shaped toward the production of virions. The new metabolism emerging in the virocell can be considered as the metabolism of the virocell itself. Notably, it can lead to the production of new metabolites that can be used as virocell markers (see below). Many examples of virocell metabolism have been reviewed in 2016 by Vardi and colleagues, and techniques such as single cell expression profiling have been specifically designed to analyse virocell metabolism. The rewiring of the cellular metabolism into virocell metabolism involves both virus encoded proteins that modulate the activity of the host enzymes, but also in many case new metabolic enzymes encoded by the virus itself (often called vAMG for virus Associated Metabolic Genes, *sensu* Mya Breitbart). An amazing example of vAMG is provided by bacteriophages infecting cyanobacteria (cyanophages). These viruses often encode components of the photosynthetic pathway that replace labile cellular counterparts, which disappear during the infection process. This allows the virocell to benefit from the energy provided by photosynthesis for the production of virions. The resulting organism is a photosynthetic virus.

In the first publication proposing the virocell concept, it was unclear if the virus itself could be equated to the virocell. Later on, it was made clear that the virus cannot be reduced to the virocell, but that: “*the term virus should describe a biological process and integrate all aspects of the viral reproduction cycle*”, i.e., the virion, the virocell, as well as silent viral genomes (proviruses) free or integrated in cellular chromosomes (Fig. 1). The difference between the virus and virocells can be nicely illustrated in the case of viruses, such as arboviruses, infecting cells from several different species of insects and vertebrates. In that case, the same viral species can produce several types of completely distinct virocells using cells from different hosts. In other cases, with the help of a human scientist, infectious virions can even be produced artificially in the absence of “natural” virocell, using *in vitro* cell lysates mimicking a virocell.

Critics of the Virocell Concept

The virocell concept has been criticized by Purification Lopez-Garcia and David Moreira who labelled it as “*a conceptual trick*” to justify considering viruses as living (see below) or else as “*epistemological cheating*”, considering that “*defining an entity (a virus) in term of itself plus a portion of another entity (a cell) is alien to logic*”. To illustrate their point, these authors suggested that defining the infected cell as a virocell is the same as to consider that a remora fish associated to a shark becomes a remora shark. This critic was refuted by pointing to the difference between a virus and extracellular (the remora) or intracellular (the *Chlamydia*) organisms living together in association (the remora and the shark) or in competition (the *Chlamydia* and the infected bacterium). In both cases, the parasitic organism maintains its organismal or cellular integrity even if its shape is profoundly modified during its reproductive cycle, as in the case of *Chlamydiae*. The latter always maintain a closed intracellular structure surrounded by a membrane, use their own ribosomes for protein synthesis and continue dividing by cell division. In contrast, the virus needs usurping the cellular territory of its victim. The virus robs the membrane of the infected cell to achieve a cellular structure and uses the host ribosomes to synthesize its proteins, transforming the infected cells into a novel cellular organism, the virocell.

The criticism according to which: “*defining an entity (a virus) in term of itself plus a portion of another entity (a cell) is alien to logic*” is valid in the framework of the virus/virion paradigm, since in this context the virus (*an entity*) is the virion (*itself*), whereas the infected cell is assimilated to another entity (*a cell*). If the virus is defined as a process that encompasses all aspects of its reproductive cycle, this criticism is no more valid. One can ask if it is legitimate to include in the virus definition an entity (the virocell) that includes components (e.g., ribosomes, many enzymes, membrane proteins and lipids) that came from the infected cell. The answer is yes, according to the philosopher Thomas Pradeu, who wrote in 2010 that: “*An organism is made of constituents that do not need to have originated in it*”.

Considering the infected cell as an unbreakable entity limits our understanding of the complex phenomenon triggered by the viral infection. This is illustrated by the ambiguity of the term “infected cell” itself. This term can *a priori* define either the bacterium, the archaeon or the eukaryotic cell infected by the virus or the virocell produced by this infection. During the infection process, the cell ‘entity’ is indeed broken since the cell contains two types of cells, the infected ribocell and the emerging virocell. The virocell concept thus requires distinguishing the infected cell from an organism. An example that illustrates this point is an amoeba infected by both intracellular bacteria and a mimivirus, which is itself infected by a virophage. In this case, four organisms, defined by four different evolutionary lineages, share the same cell. The concept of a cell as a vehicle, suggested by Matti Jalasvuori, can be useful to understand this situation. He suggests considering cells as vehicles carrying different types of replicons (cellular chromosome, plasmids and/or viral genomes). This concept can also be applied when considering cells as vehicles carrying different types of organisms.

Notably, the distinction between cells and virocells helps removing some ambiguity that are inherent to the concept of a cell as an unbreakable entity. For instance, Purificacion Lopez-Garcia and David Moreira wrote that “*viruses are evolved by cells*” to deny any active role of the virus in its own evolution. The problem with such reasoning is most obvious when considering new viral genes emerging *de novo* in infected cell, in which the cellular genome has been completely destroyed. In such situation, considering that *viruses are evolved by cells* would mean that viruses can be evolved by dead cells. In the framework of the virocell concept, the sentence *viruses are evolved by cells* remains valid if the term cell means virocell, i.e., “*viruses are evolved by virocells*”.

Diversity of Virocells

Virocells and Ribovirocells

The transformation of the host (victim) ribocell into a virocell is gradual, so that for some time two organisms, the dying host cell and the virocell, co-exist in the same cell, fighting each other (in particular via the CRISPR and anti-CRISPR systems in Archaea and Bacteria). Later on, either one of the two organisms win, or they can manage to coexist (see below). If the ribocell is entirely transformed into a virocell, the system will finally collapse since virocell is a transient organism, which will eventually disappear through self-disruption. This cannot be taken as an argument against the virocell concept since many “regular” cellular organisms also have a short lifespan. In many cases, the infected cell survives and enters into a kind of “pacific coexistence” with the virus, allowing the production of virions, a situation sometime referred to as carrier state or persistence. Cells that produce virions but that can still divide have been called ribovirocells (Fig. 1). In ribovirocell, the virus and the bacterium, the archaeon or the eukaryote have a symbiotic relationship that can be more or less beneficial for the different partners. There are thus different types of virocells, depending of the degree of autonomy and capacity maintained by the original ribocell. Single-cell analyses have shown that a population of infected cells contains in fact various subpopulations of cells expressing different subsets of cellular and viral genes, testifying for different outcomes in the virus-host arms races. Some of these subpopulations probably correspond to virocells or ribovirocells, others correspond to cells becoming resistant to the virus, allowing persistence of the host. The lysogenic state can be viewed as one of the strategies used by ribocells to survive viral infection and for the virus to wait for conditions optimal for virocell production. A lysogenic cell with an integrated or episomal viral genome that is not expressed cannot be called a ribovirocell, since it does not produce virions. As for other definitions proposed by scientists to describe the living world using classification, these definitions somehow arbitrarily divide a reality that is often more complex, virocells, ribovirocells and lysogenic cells forming a continuum, often without clear-cut borders, with overlap and the possibility to shift from one state to the other under mutational or environmental shift.

Virocells With Nucleus

Many eukaryoviruses replicate and transcribe their genomes in viral organelles that mimic the nucleus of eukaryotic cells. These viral factories can be assimilated to virocell nucleus. Beside virus factories, lipid bodies and autophagosomes produced in some infected eukaryotic cells can also serve as new forms of organelles in the virocell. The case of virocells with nuclei (synkaryotic virocells) is especially interesting. At first, it seemed that virocells without nuclei (akaryotic virocells) were only produced during the infection of prokaryotic (akaryotic) cells, archaea and bacteria, whereas synkaryotic virocells were only produced during the infection of eukaryotic (synkaryotic) cells. It came as a surprise when Pogliano and colleagues reported in 2017, that the bacteriophage $\phi 2-1$ produces a viral nucleus during the infection of the bacterium *Pseudomonas chlororaphis* (Fig. 2). The membrane of the viral nucleus is formed by a virus-encoded protein and, remarkably, this nucleus is localized at the centre of the bacterium by another virus-encoded protein, PhuZ, a homologue of eukaryotic tubulin.

Implications of the Virocell Concept

Viruses as Cradles of New Genes

The virocell concept was put forward partly to remind evolutionists that viruses are not only pickpockets of cellular genes (as usually assumed in the virus/virion paradigm) but also a cradle of new genes (thus new functions). This is because new genes

Fig. 2 (Left) Slice through a cryo-electron tomogram of *Pseudomonas chlororaphis* cell infected with phage 201φ2-1. Upon infection, the phage assembles a large protein shell containing phage DNA with capsids docked to this shell for DNA encapsidation and ribosomes excluded from the shell in the host cytoplasm. continuously arise during the intracellular stage of the virus reproduction cycle (in the virocell), when the viral genome is replicated and expressed. The mechanisms of *de novo* formation of viral genes are most likely the same as those responsible for the formation of new genes in cellular genomes. The mechanism of the emergence of new gene in DNA genomes is now well understood from comparative genomics studies performed in *Saccharomyces cerevisiae* and *Drosophila melanogaster*. Most new genes originate from the selection of short open reading frames (proto-genes) arising randomly in intergenic regions. It is likely that similar mechanisms operate in all three domains of cellular life as well as in DNA viruses. In RNA viruses, new genes can originate by overprinting on the non-coding strand of pre-existing genes, producing overlapping genes that can be unrelated from one viral strain to another. The massive *de novo* creation of viral genes explains why most viral genes have no cellular homologues.

Enumeration of Viruses in the Environment

The estimation of the abundance and importance of viruses in the environment has been traditionally done by counting virus-like particles (VLPs) using epifluorescence or flow cytometry methods. In these studies, the systematic assimilation of the VLP number to the number of viruses once again testifies to the entrenchment of the virus/virion paradigm. This strategy has been questioned on methodological grounds, considering that VLPs can also correspond to extracellular vesicles (EVs). Moreover, on the epistemological grounds, this method was considered to be misleading because, in the framework of the virocell concept: “*estimating the number of viruses by counting their virions is equivalent to counting the number of fish eggs in the ocean to estimate the number of fishes*”. The number of viruses present in the environment is thus grossly overestimated if they are assimilated to the number of VLPs and it would be more accurate to quantify viral activity in the environment by counting virocells. Unfortunately, this is a challenging task. It is much more difficult to estimate the number of virocells in the environment than to count the number of virions. The virocell number should be always lower than the total cell number since the cells detected by epifluorescence or flow cytometry include both virocells and ribocells. However, it could be a large portion of the total cell number. For instance, it has been estimated in several ecological studies that around 40% of bacteria in the ocean are lysed by viruses at any moment. This would mean that at least 40% of total cells enumerated in these environments as bacteria are in fact virocells. Vardi and colleagues proposed that detection of virocell metabolomic signature and of unique virocell-derived molecules could serve as biomarkers of virocells to estimate the impact of viruses on the chemical and microbial composition in the marine environment.

Are Viruses Living?

The debate between scientist regarding the living status of viruses has been on-going for years. The acellular nature of viruses in the virus/virion paradigm was a major argument to consider them as non-living entities because, according to André Lwoff: “*an organism is constituted of cells*”. Moreover, it was assumed that viruses could not be living since they have no metabolism. For instance, Marc Van Regenmortel wrote in 2003 that “*viruses do not possess many of the essential attributes of living organisms, such as the ability to capture and store free energy and they lack the characteristic autonomy arising from the presence of integrated, metabolic activities*”. Proponents of the idea that viruses are not living have criticized the virocell concept as a trick to bypass these traditional arguments. The notion that viruses lack the ability to capture and store free energy because they do not have an integrated metabolism is indeed valid if the virus is assimilated to the virion. In contrast, the concept of metabolising virocells emphasizes that viruses can capture and store free energy, similar to ‘regular cells’.

The philosophers John Dupre and Maureen O’Malley wrote that: “*Life arises when lineage forming entities collaborate in metabolism*”. Viruses fit this definition in the virocell framework, since they are both genetic and metabolic entities. In the course of his reflexion on the nature of viruses and their status as living organisms, the notion of a living organism and the definition of life

itself was questioned. As an example of the difficulties associated to these questions, it is not possible to determine when the transition from living to non-living organisms occurred in the case of the evolution leading from the alpha-proteobacterial ancestor of mitochondria to *bona fide* mitochondria. To maintain the concept of living “alive”, I suggested considering as living not only organisms but all biological entities “as long as they are operational in the process of life”. According to this definition, “entities” corresponds to “individuals”, i.e., objects that are “separable, countable and have acceptable clear-cut spatial boundaries” according to philosopher Stéphane Chauvier. Life can then be defined as “the mode of existence of biological individuals”. With this definition, a living individual could be a protein, a chromosome, a virion or a virocell, considered to be lineages with an evolutionary history designed by Darwinian principles of variation and selection.

Conclusions

In my opinion, the virocell concept clarifies the nature of viruses and opens new philosophical questions about the definition of life. It also has practical potential value in that it calls for reshaping of research programs in virology by putting more spotlight on the intracellular phase of the virus life cycle. Such research has the potential to identify new targets for fighting viral infections by looking for drugs active against the virocell as well as new biomarkers to analyse viral activity in the environment.

Glossary

Classification The rational process of assigning viruses to taxa.

Inclusion principle Viruses assigned to a lower taxon based on certain virus characteristics must also have the characteristics needed for classification into a higher-ranked taxon that includes the lower taxon.

Monophyletic Belonging to a group of viruses that consists of all the descendants from a common ancestor.

Nomenclature The (often controversial) assignment of names to taxa.

Polyphyletic Not being connected to a common ancestor.

Polythetic Sharing many, but not all characteristics of a common core set of characteristics.

Species Currently the lowest-ranked taxon in virus taxonomy. Not to be confused with "viruses," which are physical entities assigned to species.

Taxon A man-made category for viruses that share certain characteristics. The now commonly accepted correct plural

of "taxon" is the fake Greek "taxa" ("taxons" would actually be more correct but is not used in English).

Taxonomy Virus classification into taxa and taxon nomenclature. The term "taxonomy" is a misnomer as the term is based on Greek "τάξις [táxis]". "Taxinomy" is a better derivation but is not used in English.

Virions Particles produced by some, but not all viruses, during the viral lifecycle for transfer of the viral genome from one host cell to another. Not to be confused with "virus." Virions differ from virus particles in that the former are assumed to be infectious, whereas the latter may be non-infectious or otherwise defective

Virus A replicative non-cellular physical entity that is obliged to depend on a host cell for replication. Virus is not to be confused with "species," which are man-made categories into which viruses are classified nor be confused with "virion." which are particles that are produced by some, but not all, viruses

History of Virus Taxonomy

Early Taxonomic Developments (1886–1971)

Virus taxonomy is a virology subspecialty that addresses the grouping (classification) of viruses (physical entities) into categories (concepts) called taxa and the development and implementation of a standardized system of naming (nomenclature) for taxa.

Virus taxonomy arguably began with the discovery of "ultrafiltrable" (i.e., non-bacterial) agents today called "viruses." This discovery began in 1886, when Adolf Eduard Mayer (1843–1942) grouped a set of similar infectious diseases of tobacco plants under the name "Mosaikkrankheit des Tabaks" (German for "tobacco mosaic disease"). In 1892, Dmitrij Iosifovič Ivanovskij (1864–1920) reported that the sap of a plant affected by tobacco mosaic disease retained its infectivity even after passage through a Chamberland filter that held back most bacteria. Unaware of Ivanovskij's experiments, Martinus Willem Beijerinck (1851–1931) also observed that filtration of infectious sap did not result in sterility. In 1898, Beijerinck reported that filtered sap retained its infectious nature even after dilution and that the sap of a newly infected plant was similarly potent after passage. Beijerinck coined the term "contagium vivum fluidum" (Latin for "contagious living liquid") for this novel type of pathogen. The term "virus" (Latin for "poison"), previously used for any infectious agent or toxin, became ever more frequently used for this novel type of pathogen, variations of which were then discovered in animals (e.g., foot-and-mouth disease virus), including humans (e.g., yellow fever virus). The (partially) particulate nature of viruses was proven when Félix d'Herelle (1873–1949) reported the invention of the plaque assay for virus particle quantification in 1917, when he discovered viruses infecting bacteria. In 1935, Wendell Meredith Stanley (1904–1971) crystallized tobacco mosaic disease-causing particles and demonstrated that they consisted largely of protein. In 1939, Gustav-Adolf Kausche (1901–1960), Edgar Pfankuch, and Helmut Ruska (1908–1973) published the first-ever electron-microscopic images of virus particles, namely those of tobacco mosaic disease virus.

The first systematic classification of viruses was proposed in 1939 by Bennett on behalf of the newly formed Committee for Virus Nomenclature of the Council of the American Phytopathological Society. Accordingly, viruses were grouped by the type and morphological/cytological manifestation of symptoms they cause in their hosts, their host tropisms, their modes of transmission via disease vectors, and the antigenic, chemical, and physical properties of their particles. In 1941, a classification was suggested by Bawden that was based solely on chemical, antigenic, and morphological properties of virus particles. This suggestion was, in essence, followed by others for many years. In 1948, Francis O. Holmes (1899–1990) suggested a first all-encompassing taxonomic system that was somewhat reminiscent of that used for animals and plants. He proposed a top-rank taxon, the order “*Virales*,” that would include three suborders for viruses that infect bacteria (“*Phaginae*”), plants (“*Phytophaginae*”), or animals (“*Zoophaginae*”). Holmes further created 13 families, 32 genera, and 248 species. However, this system did not gain community support because Holmes separated viruses based on their host tropisms and ignored the considerable morphological similarities of the particles produced by all of the viruses that he separated into the 3 suborders.

From 1953–1957, André Michel Lwoff (1902–1994) created and expanded a set of criteria for the definition of “virus.” This definition informed a hierarchical virus taxonomy brought forth in 1961 by Peter D. Cooper, who divided animal viruses using particle characteristics into those that contain either DNA (“*deoxyviruses*”) or RNA (“*riboviruses*”). Further division of each group was dependent on ether sensitivity, i.e., dependent on whether the particles were wrapped in lipid envelopes (“*lipoviruses*”), or ether resistance (“*clathroviruses*”). From 1963–1967, this system was improved to incorporate virus particle sensitivity to low pH and particle shape and symmetry as classification criteria.

The first taxonomic system that received broad attention is that of Lwoff, Horne, and Tournier (the LHT system), which was first published in 1962 and finalized in 1966. The LHT system grouped viruses into one phylum (“*Vira*”) with two subphyla based on RNA or DNA presence in virions (“*Deoxyvira*” and “*Ribovira*”). Each subphylum included classes based on the symmetry of virion capsids (e.g., the classes “*Deoxyhelica*” for “*helical DNA viruses*” and “*Ribocubica*” for “*cubical RNA viruses*”). These classes were further divided into orders (“*...viraes*”) with suborders (“*...viridales*”), families (“*...viridae*”), subfamilies (“*...virinae*”), genera (“*...virus*”), subgenera (“*...virus*”), and described type species and common names for taxon members. Although none of the higher taxa stood the test of time, several family names used in the system are still used today (e.g., “*Poxviridae*,” “*Adenoviridae*,” “*Paramyxoviridae*” became the current *Poxviridae*, *Adenoviridae*, and *Paramyxoviridae*, respectively), and the suffixes for order, family, subfamily, genus, and subgenus names prevailed, albeit they are now consistently italicized (“*...viraes*,” “*...viridae*,” “*...virinae*,” “*...virus*,” “*...virus*”).

Baltimore Classification (1971)

In 1971, David Baltimore published a working classification of viruses that is still used today in parallel with official virus taxonomy. Rather than assigning viruses to taxa, Baltimore grouped all viruses into six disconnected groups without any subdivisions, now commonly referred to as Baltimore Classes (BCs). BCs were established based on the type of nucleic acid incorporated into virions, and thereby on the type of virus reproduction:

- (1) BC I: viruses with double-stranded DNA genomes that have a replication-expression strategy highly reminiscent of that of cellular organisms (e.g., *Adenoviridae*);
- (2) BC II: viruses with single-stranded DNA genomes (e.g., *Geminiviridae*);
- (3) BC III: viruses with double-stranded RNA genomes (e.g., *Reoviridae*);
- (4) BC IV: viruses with positive-sense RNA genomes (e.g., *Picornaviridae*);
- (5) BC V: viruses with negative-sense RNA genomes (e.g., *Paramyxoviridae*);
- (6) BC VI: viruses with positive-sense RNA genomes that replicate via DNA intermediates produced by reverse transcription of the genome (e.g., *Retroviridae*);
- (7) BC VII (added later to the original system): viruses with double-stranded DNA genomes that package a double-stranded DNA form or an RNA-DNA hybrid into virions and replicate via reverse transcription (e.g., *Hepadnaviridae*).

Until recently, BCs have been widely referred to as informal highest ranks of virus classification and the individual BCs were widely assumed to be monophyletic. However, recent studies (e.g., Wolf *et al.*, Koonin *et al.*) call this assumption into question. Although the partitioning of viruses into BCs will remain highly useful for teaching purposes, BCs are unlikely to be used as top ranks in official virus taxonomy.

Current Virus Taxonomy (1971–Present)

Influenced by the publication of the LHT system, the virology community clearly felt an urgent need for an official virus taxonomy. Consequently, at the 1966 International Congress for Microbiology in Moscow, the Executive Committee of the International Association of Microbiological Societies (IAMS) established the International Committee on Nomenclature of Viruses (ICNV) to develop a globally respected and applicable virus taxonomy for all virus types of all life forms. The ICNV, which in 1974 became today's International Committee on Taxonomy of Viruses (ICTV) under the International Union of Microbiological Societies (IUMS, the successor to IAMS), published its First Report in 1971. From then on until the present, virus taxonomy (today including not only viruses but also viroids and satellites) has been under the jurisdiction of this committee. The vast majority of virology and microbiology specialty journals request (but unfortunately rarely enforces) that manuscript authors follow the official ICTV taxonomy.

Contrary to the LHT system, which approached virus classification from the top taxonomic rank downwards, the ICNV/ICTV established a hierarchical virus taxonomy from the lowest taxonomic rank upwards. This approach was taken because, at the time, hallmark properties common to all viruses (akin to, for instance, 16S rRNA of bacteria or mitochondrial DNA of animals) were unknown. Genome sequence information for most viruses was lacking, and, therefore, phylogenetic analyses were impossible to perform. In addition, high mutation rates and horizontal gene transfer obscured relationships between virus groups.

From the initiation of ICTV's classification efforts, viruses (from hereon, including viroids and satellites) were suspected to be polyphyletic. Thus, the probability of being able to join large groups of viruses under higher-rank taxa using demonstratable evolutionary relationships appeared low. Consequently, viruses were grouped according to the morphological, biophysical, and biochemical properties of their virions and the "phenotype" of infections. After the advent of increasingly efficient genome sequencing methodologies, viruses were grouped according to viral genomic sequences and phylogenetic relationships to one another within relatively closely related virus sets. The result of these activities were numerous individual taxonomic hierarchies for viruses, typically up to the family rank, that were not connected to each other at a top rank.

The historical development of the official ICTV virus taxonomy can be reviewed in published ICTV Reports and interim updates that typically have been published in *Archives of Virology's* Virology Division News (VDN). The latest (10th) ICTV report has been published open-access online and is continuously updated at least annually. Announcements for major updates to the report have been and are being published continuously as Taxonomic Profiles in *The Journal of General Virology*.

The first ICTV report listed only 2 families, 27 genera, 10 subgenera, and 18 "virus groups", but the classification scheme has expanded considerably since then. For instance, the first order (*Mononegavirales*) was established in 1991, and in 2019 the first phylum (*Negarnaviricota*) and realm (*Riboviria*) were made official. By that time, 5560 species had been established (Table 1).

Despite this extension of taxon ranks and associated taxa, many families are currently "free floating" (i.e., families not connected to other families at higher taxonomic ranks). However, the majority of RNA viruses have been assigned to the highest available rank, realm. This assignment was based on the recognition that all these RNA viruses have genomes that share a common viral hallmark gene (VHG), namely one that encodes an RNA-directed RNA polymerase (RdRp) and that these polymerases form a monophyletic group (Fig. 1).

As shown in Fig. 1, most RNA virus families and orders could be grouped into major branches, but these branches have not yet received official status, except for Branch 5. Branch 5, established for negative-sense RNA viruses, is now officially recognized by the ICTV as phylum *Negarnaviricota*. This phylum is currently the only example of a top-down virus taxonomy of all available principle/primary ranks and, thereby, places the viruses of all included taxa into relationship to each other (Fig. 2).

Aside from expanding the number of available ranks and filling them with increasing numbers of taxa and numerous incremental improvements, current virus taxonomy underwent two additional major changes compared to historic efforts:

Table 1 Scope of the official ICTV taxonomy as ratified in spring of 2019. Listed are all permitted principle/primary taxon ranks (black), secondary ranks (grey), and the number of currently established (but not necessarily interconnected) taxa within these ranks. Ranks are ordered from lowest (top, species) to highest (bottom, realm) similar to the classical "Tree of Life" in which the highest ranks are depicted as the tree trunk close to earth and the lowest ranks are depicted as the finest branches up in the canopy. Intra-taxon divergence is high at the highest ranks and low at the lowest ranks

Rank	Number of established taxa
Species	5,560
Subgenus	59
Genus	1,019
Subfamily	79
Family	143
Suborder	7
Order	14
Subclass	0
Class	6
Subphylum	2
Phylum	1
Subkingdom	0
Kingdom	0
Subrealm	0
Realm	1

Fig. 1 Phylogenetic analysis of RNA virus RNA-directed RNA polymerases (RdRps) by Wolf *et al.*

Fig. 2 Current taxonomy of *Negarnaviricota*. Due to space constraints, the current family/genus composition of *Mononegavirales* and *Bunyavirales* are not shown, and species have been omitted.

- (1) In 1991, the ICTV embraced the idea that “virus species” should be conceptually differentiated from “viruses” and that the biological concept of “species” as it has been applied to botanical, mycologic, prokaryotic, and zoologic taxonomy is also universally applicable to virus taxonomy. “Virus species” was first defined as “...a polythetic class of viruses that constitutes a replicating lineage and occupies a particular ecological niche” by van Regenmortel. Currently, “[a] species is the lowest

taxonomic level in the hierarchy approved by the ICTV. A species is a monophyletic group of viruses whose properties can be distinguished from those of other species by multiple criteria". Both species definitions have been highly controversial, and discussions continue on how to improve them. However, scientists broadly agree that the lowest rank of species is needed.

- (2) In 2017, the ICTV acknowledged that most viruses of the global virome are unlikely to ever be cultured or otherwise characterized in a laboratory. Hence, the ICTV accepted virus classification based on information deduced from an at least coding-complete virus genome sequence. This step expanded the classification to include numerous viruses known only from metagenomic datasets and, thereby, opened the door for sophisticated phylogenetic analyses and a vastly improved official description of the virosphere. Importantly, this step by the ICTV only means that the minimum requirement for virus classification is the availability and analysis of a coding-complete virus genome, but it does empathetically not exclude taking other virus characteristics, such as particle morphologies, tissue and host tropism, or infection phenotype, into consideration.

The International Committee on Taxonomy of Viruses (ICTV)

Organization

The ICTV, a non-profit organization, is the only committee of the Virology Division of the IUMS. Contrary to common perception, the ICTV is a relatively large, international organization, and ICTV decisions are achieved in a highly democratic manner based on majority voting at multiple steps involving representatives of the global virology community. The ICTV Executive Committee (EC) consists of 19 elected members with term limits, including a President, a Vice-President, several Secretaries, and 6 Subcommittee Chairs who are experts for large groups of viruses of all cellular organisms. Next to the EC, the ICTV consists of 11 elected Life Members (experts who contributed significantly to the development of virus taxonomy in the past), 42 nominated National Members (national representatives of international microbiological or virologic IUMS member societies), and 101 Study Group Chairs. The latter are ICTV members appointed by EC Subcommittee Chairs, typically for a maximum of two 3-year terms, to assemble an unlimited number of experts, who are not part of the ICTV, but who have specific expertise on viruses of, typically, a viral family or order. All ICTV members perform their duties voluntarily without pay.

Official statutes outline the ICTV remit, actions, and interactions within ICTV and with the community, and a code, the International Code of Virus Classification and Nomenclature (ICVCN), outlines the official rules and recommendations for virus classification into taxa and taxon nomenclature. Importantly, the ICTV is currently not responsible for the nomenclature of viruses (their names and abbreviations) or their subclassifications into isolates, strains, variants, genotypes, serotypes, lineages, or clades. Since no other organization exists that authoritatively administers these community needs, this lack of ICTV responsibility continuously causes confusion and often frustration among virologists who consider these needs part of virus taxonomy.

Taxonomic Process

Contrary to common perception, the ICTV does not impose taxa on the virology community but instead evaluates, votes on, and administers submitted taxonomic proposals (TaxoProps) originating from the virology community. TaxoProps can be submitted electronically to the ICTV at any time by any individual, whether (s)he is a member of the ICTV or not. Populating a TaxoProp is straightforward and guided by standardized Microsoft Word and Excel templates with associated instructions that can be downloaded from the ICTV homepage. Ideally, TaxoProps are submitted to the ICTV by the authors of a scientific research article describing a novel virus or providing novel information on the evolutionary relationships of a known virus. Under these circumstances, the virus discoverers can weigh in on classification and nomenclature discussions. However, virus discoverers do not have to be consulted during the classification process, and, hence, anybody can propose the classification or reclassification of any virus at any time. Typically, the annual deadline for TaxoProp submission is set for a day in June—TaxoProps submitted prior to this date will be considered by the ICTV typically in July; whereas TaxoProps submitted after the submission deadline will be considered in July of the subsequent calendar year.

Submitted TaxoProps undergo several steps of scrutiny:

- (1) After submission to the ICTV, the TaxoProp is forwarded to the most appropriate EC Subcommittee Chair. For instance, a TaxoProp will be forwarded to the EC Bacterial and Archaeal Viruses Subcommittee Chair if the TaxoProp addresses a bacterial virus. The Subcommittee Chair will perform an initial review on whether the proposed taxonomy conforms to current ICVCN rules and whether the TaxoProp is complete with the information necessary for further evaluation. If necessary, the Subcommittee Chair will request additional information or edits from the TaxoProp author(s);
- (2) Once satisfactory to the EC Subcommittee Chair, the TaxoProp is forwarded to the most appropriate Study Group of the EC Subcommittee Chair's subcommittee (either via the Study Group Chair or directly to all Study Group members). For instance, a TaxoProp proposing the classification of a new bacterial virus into *Microviridae* would be forwarded to the ICTV *Microviridae* Study Group. The Study Group then performs an in-depth scientific review of the proposal and then recommends the acceptance, rejection, or need for revision to the Subcommittee Chair. The chair then once more communicates with the TaxoProp authors to improve the TaxoProp. Ideally, this process is repeated until both EC Subcommittee Chair and Study Group (per majority vote) are satisfied with the proposal or have reached a consensus that it needs to be deferred or rejected.

Study Groups therefore serve as mediators between their respective virologist constituency (their virus “subcommunity”) and the ICVCN requirements and concerns of the ICTV. However, an ICTV Study Group does not have veto power. On rare occasion, Study Group recommendations may be overruled by the Subcommittee Chair to prevent gridlock;

- (3) The TaxoProp, if appropriate with comments summarizing EC Subcommittee Chair and/or Study Group concerns or dissent, is then forwarded to the ICTV Proposals Secretary. The Proposals Secretary will once again review the documents for adherence to the ICVCN Rules and TaxoProp preparation guidelines and then post the TaxoProp for public scrutiny online on the ICTV homepage. Public comments on the TaxoProp can be posted directly to the homepage. TaxoProps submitted right before the submission deadline will be visible to the public for at least 4 weeks;
- (4) The TaxoProp will then be distributed to the entire EC for review prior to the annual EC meeting and then be presented in person to the entire EC by the Subcommittee Chair together with his or her recommendation regarding acceptability. The EC then discusses the TaxoProp and, per majority vote, decides whether the TaxoProp is approved, requires further revisions, needs to be deferred for discussion to the next EC meeting in the following calendar year, or rejected. The decision is communicated to the TaxoProp authors (and the public via the ICTV homepage) and the authors are given approximately 8 weeks to revise the TaxoProp if revisions were requested. EC voting is then repeated per email, and the TaxoProp is either accepted, deferred, or rejected;
- (5) EC-accepted TaxoProps are posted once again on the ICTV homepage for public scrutiny. Then, typically around February of each year, the entire ICTV is requested to ratify or reject the EC recommendation by majority email voting. If ratification occurs, the proposed taxonomy becomes official taxonomy and is communicated to the virology community via a VDN taxonomy update article published by the EC, via updates on the ICTV homepage, and by posting a new, so called Master Species List (MSL) on the ICTV homepage.

Virus Classification

Virus classification is the gathering of viruses into progressively more inclusive groups (lower taxa included in higher-ranked taxa) based on common genomic, phylogenetic, and phenotypic properties that, ideally, are proof of evolutionary relationships or descent. As a result, very closely related viruses may be assigned to distinct species that are all included in the same genus, whereas unrelated viruses may be assigned to distinct species that are included in separate realms. The (typically ICTV Study Group-recommended) criteria for virus classification and the demarcation criteria that are used to decide whether a virus belongs to an already established taxon or requires the establishment of a new taxon are modified continuously based on improved understanding of virus micro- and macroevolution. These criteria often differ between taxa because distinct virus groups evolve with different speeds depending on their genome types, absence or presence of replication proof-reading mechanisms, and propensity to reassort genome segments and/or to engage in horizontal gene transfer. By today, no general methodology for virus classification is commonly accepted. Some ICTV Study Groups recommend complete-genome pairwise sequence comparisons to establish percentage similarity cut-offs for taxon demarcation. However, others Study Groups focus on the phylogenies of certain hallmark features (e.g., the core domain of RNA-directed RNA polymerases), concatenated open reading frames, network analyses of structural features of hallmark proteins, or phenotypic features of viruses. Such features may include host tropism, receptor usage, or type of induced host disease. The current classification criteria for viruses of a particular taxon can be found in the most recent ICTV Report.

Differentiating Taxa and Viruses

In virus taxonomy, viruses and taxa need to be strictly differentiated. Within the ICTV, the current majority view is that taxa are man-made categories or “concepts of the mind”, i.e., they are not physical entities. Accordingly, taxa serve as conceptual perfect averages of all physical members that have ever existed, exist, or will exist independent of imperfections of individual members. Therefore, taxa, such as species or families, cannot be discovered or eradicated, and they cannot be studied, infect people, or become infected. Taxa can only be established or abolished. Taxa are represented by physical entities, i.e., viruses, which can be discovered, isolated, studied, used for infections, and eradicated. This view is not necessarily shared by everyone and the discussion about the “nature” of species and whether species can be considered physical entities continues throughout biology.

Nomenclature

Virus Taxa

In biological taxonomies, nomenclature is the process of assigning specific, ideally unique, names to organisms (e.g., “lion”) and to the taxa to which these organisms have been assigned (e.g., lion → “*Panthera leo*”). The primary function of these names is to serve as unique identifiers, i.e., labels, that aid in written and oral communication among scientists about specific groups of organisms. Since people are generally more adept to memorizing (even artificial) names than numbers even in the short term (e.g., while reading a manuscript or listening to a seminar), taxon names typically consist of words rather than numbers. In the case of taxa, specific suffixes may indicate the rank of the named taxon.

Table 2 Rank-specific suffixes for virus taxon names

Rank	Rank-specific suffixes for taxon names	Example
Genus/Subgenus	... <i>virus/virus</i>	<i>Ephemerovirus/Sarbecovirus</i>
Subfamily	... <i>virinae</i>	<i>Rubulavirinae</i>
Family	... <i>viridae</i>	<i>Geminiviridae</i>
Suborder	... <i>virineae</i>	currently none
Order	... <i>virales</i>	<i>Herpesvirales</i>
Subclass	... <i>viricetidae</i>	currently none
Class	... <i>viricetes</i>	<i>Monjiviricetes</i>
Subphylum	... <i>viricotina</i>	<i>Polyploviricotina</i>
Phylum	... <i>viricota</i>	<i>Negarnaviricota</i>
Subkingdom	... <i>virites</i>	currently none
Kingdom	... <i>virae</i>	currently none
Subrealm	... <i>vira</i>	currently none
Realm	... <i>viria</i>	<i>Riboviria</i>

Table 3 Species names in non-virologic taxonomies

Taxonomy type	Example species	Organism assigned to example species
Botanical	<i>Arabidopsis thaliana</i> (L.) Heynh.	Thale cress
Mycological	<i>Pleurotus ostreatus</i> (Jacq.) P. Kumm., 1871	Pearl oyster mushroom
Prokaryotic	<i>Escherichia coli</i>	<i>Escherichia coli</i>
Zoologic	<i>Pan troglodytes</i> Blumenbach, 1775	Common chimpanzee

The ICTV only administers the nomenclature of virus taxa, but not the nomenclature (names or abbreviations) of viruses. Virus taxon nomenclature is regulated by the rules of the ICVCN, which stipulate, for instance, that

- (1) all taxon names are to be capitalized, italicized, and never abbreviated (e.g., *Caudovirales*, *Paramyxoviridae*);
- (2) each taxon name with the exception of names of species may consist only of a single word; and
- (3) all taxon names are to be written in the standard Latin alphabet without diacritical marks.

The rank affiliation of virus taxa is identifiable by rank-specific suffixes appended to taxon names (Table 2). Exceptions are subgenera, which have names with the same suffix as genus names, and species names, which have yet to be standardized.

ICTV nomenclature differs in several aspects from other biological taxonomies. Akin to prokaryotic taxonomy, virus taxonomy requires the italicization of all taxon names, whereas only genus and species names are italicized in botanical, mycological, and zoological taxonomies. In addition, all non-virologic organismal taxonomies, such as botanical, mycological, prokaryotic, and zoological taxonomies, use the so-called Linnaean binomial species format, i.e., a species name consists of two italicized, Latinized words separated by a space. The first (capitalized) word, is the genus name whereas the second (lower-case) word is the so called-species epithet. Depending on the taxonomy, these binomial names are followed by a so-called authority, i.e., typically the last name and year (or an abbreviation thereof) of the person who first established the taxon (Table 3).

The ICTV is currently evaluating whether a similar binomial species naming format should be mandated for virus species names because as of now, virus species naming is chaotic and thereby contributing to the continuous confusion between virus species and viruses (Table 4).

However, each virus species name is required to begin with a capitalized word and all other words are to be written in lower case except if they are proper nouns. Taxon names that have been suggested or official proposed but not yet accepted by the ICTV should be indicated by quotation marks (e.g., "*Autolykiviridae*", "*Megavirales*").

Viruses

Although nomenclature of viruses is not regulated by the ICTV, the ICTV does recommend adherence to certain rules:

- (1) Virus names should not be italicized, and the individual words of a virus name should not be capitalized except if they are proper nouns (Table 4).
- (2) Virus names may be abbreviated (Table 4).
- (3) Virus names and virus name abbreviations ought to be unique.
- (4) The names of groups of viruses belonging to taxa ranked higher than species, such as all members of a family, should be derived from the taxon name (e.g., the members of *Flaviviridae* are called flaviviruses and the members of the order *Nidovirales* are called nidoviruses). Rank-specific suffixes for members of taxa ranked higher than genus have thus far only been suggested

Table 4 Non-exhaustive list of currently used species naming formats in virus taxonomy

Species format	Example	Virus assigned to example species
Identical in spelling to the name of the member virus and only differentiated from that name via italics and, sometimes, capitalization	<i>Cafeteria roenbergensis virus</i>	Cafeteria roenbergensis virus (CroV)
Mimics virus name but is more or less distinct from the name of the member virus	<i>West Nile virus</i>	West Nile virus (WNV)
	<i>Pseudomonas virus D3112</i>	Pseudomonas phage D3112
	<i>Seneca virus A</i>	Seneca Valley virus (SVV)
	<i>Severe acute respiratory syndrome-related coronavirus</i>	severe acute respiratory syndrome coronavirus (SARS-CoV)
Non-Latinized binomial with identical suffixes in both word components	<i>Senegalvirus marseillevirus</i>	Senegalvirus
Non-Latinized genus-species binomial with species epithets being numbers or letters	<i>Aalivirus A</i>	aalivirus A1 (AalV-A1)
Non-Latinized genus-species binomials	<i>Sanfarnavirus 1</i>	
Non-Latinized genus-species multinomial	<i>Alphaarterivirus equid</i>	equine arteritis virus (EAV)
Non-Latinized species-genus binomial	<i>Etaarterivirus ugarco 1</i>	Kibale red colobus virus 2 (KRCV-2)
Non-Latinized species-genus trinomial containing numbers or letters at different positions	<i>Lassa mammarenavirus</i>	Lassa virus (LASV)
	<i>Avian orthoavulavirus 1</i>	avian paramyxovirus 1 (APMV-1)
	<i>Mammalian 1 orthobornavirus</i>	Borna disease virus 1 (BoDV-1)
Non-Latinized species-genus trinomial or multinomials using words	<i>Calla lily chlorotic spot orthotospovirus</i>	calla lily chlorotic spot virus (CCSV)
	<i>Tai Forest ebolavirus</i>	Tai Forest virus (TAFV)
	<i>Lausannevirus</i>	Lausannevirus

for subfamily (“...virins”, e.g., rubulavirins), family (“...virids”, e.g., flavivirids), and order (“...virads”, e.g., nidovirads) but have not yet been widely accepted in the virology community.

The ICTV Virus Metadata Resource (VMR) is a developing resource in which virus names, virus name abbreviations, exemplar isolates, and GenBank accession numbers can be located in association with the taxa to which particular viruses are currently assigned.

Future Developments

Several steps are currently under discussion that, potentially, could bring virus taxonomy in harmony with other biological taxonomies. These include the operational definition of the term “virus” for improved delineation of the ICTV mandate (e.g., if plasmids or satellite RNAs or endogenous virus-like elements were considered viruses, then they ought to be classified); the possible inclusion of virus nomenclature in the ICTV mandate; the development of rank-specific suffixes for vernacular names for the groups of viruses belonging to taxa of all ranks; and the establishment of a mandated Linnaean (Latinized binomial) species naming format.

The acceptance of *Negamaviricota* based on the analysis depicted in Fig. 1 already points toward a path forward to classify all viruses of *Riboviria* into principal/primary ranks, with each depicted branch likely representing a unique phylum. In addition, the viruses of several taxa, such as animal viruses of *Herpesvirales* and the prokaryotic viruses of *Caudovirales*, have long been considered as related and therefore should be joined at higher ranks. Consequently, in 2020, Koonin *et al.* outlined the first systematic top-down virus taxonomy since the LHT system. Accordingly, a total of four realms would be needed to classify most currently known viruses at all available principle/primary ranks. The establishment of the realms was proposed to be justified based on the discovery of specific viral hallmark genes that can be used to evolutionary connect all their constituent viruses: (1) RdRps and RNA-directed DNA polymerases (RdDps) for most RNA viruses (*Riboviria*); (2) replication initiator proteins (Reps) of the His-hydrophobic-His (HUH) superfamily for all single-stranded DNA viruses; (3) vertical jelly-roll capsid proteins for many double-stranded DNA viruses; and (4) HK97-fold capsid proteins for viruses classified in *Caudovirales* and *Herpesvirales*. If accepted by the ICTV, virus classification would finally begin to resemble the classification schemes of cellular organisms. Nevertheless, the establishment of four separated realms would still attest to the polyphyly of viruses, although it suggests that viruses emerged only a few times in evolutionary history (viruses would be “mistletoe on the tree of life”).

Finally, procedural improvements might ensure improved communication of the ICTV with the virology community and thereby increased efficiency of the ICTV. Such improvements may include automatic classification algorithms, fully online TaxoProp submissions and evaluation systems, harmonization of classification criteria across taxa, and faster ratification cycles.

Introduction

All cellular organisms, with the possible exception of some intracellular parasitic bacteria, host diverse obligate intracellular parasites and symbionts including viruses and virus-like mobile genetic elements (MGEs). Viruses are the most abundant biological entities on earth: the total number of virus particles at any given moment reaching the mind-boggling value of 10^{31} , which is about an order of magnitude greater than the total number of cells. Lysis of cells, primarily, bacteria, resulting from virus infection is a major biogeochemical factor. On par with their physical abundance, viruses also represent the largest pool of genetic diversity in the biosphere that constantly supplies genes to cellular life forms. Theoretical arguments suggest that genetic parasites inevitably emerge in even the simplest replicator systems. The ubiquity of viruses in the biosphere and their enormous diversity, along with the theoretical argument on the inevitable emergence of genetic parasites in any replicator system, imply viruses and other MGEs have been major players in the evolution of life for its entire duration.

A defining feature of the virus world is the diversity of the replication and expression strategies among viruses and MGEs (Fig. 1). All possible forms of nucleic acids and their interconversions are employed in the virus world, in a dramatic contrast with the uniform route of information transfer in cellular organisms (Fig. 1). In 1971, David Baltimore published a classification scheme that divided all viruses into 6 classes (a 7th class has been added subsequently). These “Baltimore classes” of viruses differ by the form of nucleic acid that is incorporated into virions (the virus genome):

- (1) dsDNA viruses that mimic the replication-expression strategy of cellular life forms;
- (2) ssDNA viruses that typically replicate via a rolling circle mechanism;
- (3) double-stranded (ds) RNA viruses;
- (4) positive-sense (+)RNA viruses in which the genome is a single-stranded (ss) RNA of the same polarity as the mRNA(s) for virus proteins;
- (5) negative-strand (−)RNA viruses in which the genome is an ssRNA complementary to the mRNA (or, in some groups of viruses, an ambisense RNA);
- (6) RNA-containing reverse-transcribing viruses with a (+)RNA genome that, however, is replicated via a DNA intermediate that is produced by reverse transcription of the genome; and
- (7) DNA-containing reverse-transcribing viruses that also replicate via reverse transcription but package the dsDNA form or an RNA-DNA hybrid into virions.

The Baltimore classes widely differ in their abundance, the diversity of the constituent viruses and other MGEs, and spread among cellular life forms. The two most abundant and diverse of the Baltimore classes are dsDNA viruses that dominate the prokaryotic virome and (+)RNA viruses that are most common in eukaryotes. However, each of the remaining 5 Baltimore classes also is abundant in at least some hosts as exemplified by the prominence of reverse-transcribing viruses in animals.

For several decades, the “Baltimore classes” have been used as an informal highest rank of virus classification. However, the partitioning of viruses into these classes is not, intrinsically, an evolutionary classification. The actual evolutionary relationships among viruses and MGE are studied by the same methods of molecular phylogenetic and phylogenomics that are employed for the study of the relationships among cellular life forms. However, major differences exist between the organizations of the cellular and viral genetic spaces. Even in cellular organisms, the genomes evolve in highly dynamic regimes and display remarkable plasticity, especially in the case of prokaryotes where horizontal gene transfer resulting in extensive gene gain as well as gene loss is a dominant evolutionary process. Nevertheless, all cellular life forms share about 100 universal genes that, mostly, encode protein and RNA components of the protein translation system. The existence of these universal, core genes represents irrefutable evidence of a common ancestry of all cellular life and provides the material for the construction of phylogenetic trees that reflect the central vertical trend in the evolution of cellular organisms and can be used as the framework for evolutionary reconstructions.

In contrast, viruses and MGE lack universal genes and even genes that are conserved in the majority of the genomes. Clearly, a single last common ancestor of viruses never existed, and instead, viruses have evolved on at least several independent occasions. Even when a gene is shared by diverse groups of viruses, it cannot be automatically assigned to their last common ancestor. The uncertainty comes from the fact that viruses continuously capture genes from their cellular hosts, and many cases of independent, convergent acquisition of homologous genes by widely different viruses have been identified. In addition, due to the typical fast evolution of virus genomes, homologous genes in viruses of different groups are often highly diverged such that detection of homologs requires the use of the most powerful methods for protein sequence analysis, and yet, comprehensive identification of homologs remains elusive.

All the problems notwithstanding, large scale evolutionary reconstruction for viruses is both feasible and informative. Although any search for a single common ancestral virus is futile, extensive analyzes of the evolution of large groups of viruses have proved

Fig. 1 Information transfer in viruses and the Baltimore classes. The replication-expression-encapsidation scheme, with some of the virus hallmark proteins involved, and the host range are shown for each class. Abbreviations in the schemes: E, encapsidation; JRC, jelly roll capsid (protein); Pr-Pol, protein-primed polymerase; R, replication; RCR, rolling circle replication; RdRp, RNA-dependent RNA polymerase; S3H, superfamily 3 helicase; T, translation; Tr, transcription. Abbreviations in the host range icons: A, archaea; B, bacteria; Mz, metazoa; UE, unicellular eukaryotes; P, plants. From Koonin, E.V., Senkevich, T.G., Dolja, V.V., 2006. The ancient virus world and evolution of cells. *Biology Direct* 1, 29, reproduced under Creative license.

productive. The principal approach employed in such studies is phylogenetic analysis of genes that are conserved across broad ranges of viruses, known as Virus Hallmark Genes (VHGs), and using the VHG phylogenies as a scaffold for the reconstruction of the history of gain and loss of other genes. A complementary approach involves dissection of networks of virus genes sharing into distinct modules. During the last few years, these approaches, perhaps, unexpectedly, have produced fairly detailed and well-substantiated evolutionary reconstructions for all Baltimore classes.

Virus Hallmark Genes

Although there are no universally conserved genes among viruses and MGEs, the distribution of the gene frequencies in viruses is strongly skewed: most of the genes are found only in small groups of viruses but a small set of VHGs includes widespread genes. Not unexpectedly, VHGs encode proteins that are responsible for the key functions in virus replication and virion structure formation. Most of the VHGs are limited to a single Baltimore class but several show a broader spread, spanning two or even more

Fig. 2 Virus hallmark genes and the Baltimore classes. For each Baltimore class, the characteristic hallmark genes (not necessarily present in all viruses of the class) are indicated. The “super-hallmark” genes are highlighted in red. Abbreviations: AEP, archaeo-eukaryotic primase; CapE, capping enzyme; DJR-CP, double jelly roll capsid protein; DNAP, DNA polymerase (family B); ds-CP, capsid protein of dsRNA viruses; FtsK-ATPase, DNA packaging ATPases of the FtsK family; Gag-CP, capsid protein of reverse-transcribing viruses, domain of Gag polyprotein; HK97-CP, HK97-like capsid protein; HUH-Endo, rolling circle replication initiation endonuclease (HUH family); Int, integrase; RdRp, RNA-dependent RNA polymerase; RT, reverse transcriptase; SJR-CP, single jelly roll capsid protein; TerL, terminase, large subunit; TerS, terminase, small subunit; Ulp1-Pro, thiol protease homologous to Ulp1 family of deubiquitinating enzymes; S1H, S2H, S3H, helicases of superfamilies 1, 2, and 3.

of the Baltimore classes (Fig. 2). These “super-VHGs” are: (1) RdRps that appear to comprise a monophyletic group of Palm domain polymerases and links the 3 Baltimore classes of RNA viruses (III-V), (2) RTs that unify the two Baltimore classes of reverse-transcribing viruses (and related MGEs), those with RNA and DNA genomes (VI and VII), and is also homologous to the RdRp, (3) Superfamily 3 helicases (S3H), distinct helicases found (almost) exclusively in MGEs including diverse (+)RNA viruses, most of the ssDNA viruses, and many dsDNA viruses, (4) Single jelly-roll capsid proteins (SJR-CPs), the dominant type of capsid proteins in positive-sense ssRNA viruses and ssDNA viruses (Baltimore classes II and IV); (5) Double jelly-roll capsid proteins (DJR-CPs), which are most common among dsDNA viruses and represented also in some ssDNA viruses; and (6) rolling-circle replication initiation endonucleases (RCREs) found in the vast majority of ssDNA viruses (Baltimore class II) but also in some dsDNA viruses (Baltimore class I).

The VHGs appear to widely differ with respect to evolutionary origins. The RdRp, RT, and RCRE, in all likelihood, descend directly from the primordial pool of replicators, given the lack of orthologs of non-viral origin in cellular life forms; S3Hs and SJR-CPs appear to be ancient recruitments of cellular proteins; the DJR-CPs apparently evolved from SJR-CPs in an ancient virus lineage. Regardless of their specific origins, the VHGs undoubtedly entered the virus world and became essential for virus reproduction at early stages of evolution. Therefore, analysis of the evolutionary histories of the VHGs is indispensable for understanding evolution of viruses and the organization of the virus world.

Evolutionary Relationships Within and Between the Baltimore Classes

RNA viruses

The three Baltimore classes that consist of RNA viruses share a single VHG, the RdRp. The sequences of the RdRps are extremely divergent between the three classes. Nevertheless, extensive comparisons of thousands of diverse RdRp and RT sequences as well as the structures of these polymerases from diverse RNA viruses and retroelements have led to an unequivocal conclusion on their monophyly among the Palm domain enzymes. Phylogenetic analyzes of protein families with such a high level of divergence as observed among the RdRps and RTs require extreme caution in interpretation. All the caveats notwithstanding, the tree of the RdRps, in which the most highly conserved RTs, those of group II introns, were included as the outgroup, shows a distinct structure (Fig. 3). The RdRps split into 5 major branches, two of which consist solely of (+)RNA viruses, one combines (+)RNA and dsRNA viruses, the fourth one includes dsRNA viruses, and the fifth one encompasses all (−)RNA viruses (Fig. 3). The monophyly of each of the 5 branches is strongly supported whereas the relationships between the branches are much less clear. The RdRp is the signature of RNA viruses that binds them all together but other genes mark each of the 5 branches and the major sub-branches within those. To confound the evolutionary reconstruction, multiple gene exchanges between RNA viruses from different branches seem to have occurred.

Branch 1 in the RdRp tree consists of the (+)RNA bacteriophages (family *Leviviridae*), one of the 2 groups of RNA viruses that infect prokaryotes, namely, a narrow range of bacteria. In addition to the leviviruses, this branch includes the RdRps of their

Fig. 3 Schematic phylogenetic tree of the RNA-dependent RNA polymerases of RNA viruses. The tree is rooted with reverse transcriptases of group II introns and non-LTR retrotransposons. The 3 Baltimore classes of RNA viruses are color-coded: blue, (+)RNA; magenta, dsRNA; yellow, (–)RNA. Negarnaviricota, for (–)RNA viruses, is the first formally established virus phylum.

descendants that infect eukaryotes. Apparently, the leviviruses first gave rise to “minimal”, naked replicons that only encode the RdRp and are known as narnaviruses and mitoviruses (both included in the family *Narnaviridae*) although these are not bona fide viruses because they do not form virions. As could be expected of direct descendants of prokaryotic viruses, mitoviruses reproduce in the mitochondria and, most likely, were captured by early eukaryotes from the mitochondrial endosymbiont. Subsequently, these agents were lost from most eukaryotic lineages, surviving only in fungi and some plants. Narnaviruses escaped from mitochondria to the cytosol of eukaryotic cells, and their descendants reentered the world of true viruses by acquiring the gene encoding SJR-CP and, in some lineages, also a movement protein and a helicase. These derivatives of the levivirus-related naked replicons are known as ourmia-like viruses that, although initially thought to be confined to plants, appear to infect invertebrates as well as shown in recent metagenomic studies. Thus, the reconstructed evolutionary scenario for this branch includes a loss of the structural module of the leviviruses (genes for the unique major and minor capsid proteins), yielding naked replicons that subsequently captured an unrelated capsid protein, SJR-CP, from plant viruses.

Branch 2 in the RdRp phylogeny encompasses a vast collection of diverse (+)RNA and dsRNA viruses that are associated with the previously described “picorna-like supergroup”, after picornaviruses, a large, well-characterized family of animal viruses that includes many human pathogens, such as poliovirus. Viruses in this branch have enormously divergent genome lengths, gene compositions, and genome organizations, and produce several types of virions with dissimilar morphologies. This branch includes both viruses with the largest known RNA genomes, nidoviruses, and those with some of the smallest genomes, such as sobemoviruses. Although no genes other than the RdRp are shared by all viruses in this branch, the two hallmark genes encoding SJR-CPs and trypsin-like proteases, appear to be ancestral features. Evolution of the viruses in this branch seems to have involved parallel capture of helicases of three different superfamilies and of a variety of additional genes, most notably, in the nidovirus lineage.

Arguably, the most notable aspect of this RdRp branch is that it combines two Baltimore classes, with a clade of dsRNA viruses that includes picobirnaviruses and partitiviruses embedded among (+)RNA viruses. Both these families of dsRNA viruses have

small, bipartite genomes, one segment encoding the RdRp and the other one encoding the CP that appears to be homologous to the CPs of other dsRNA viruses such as reoviruses. This clade of dsRNA viruses also includes naked RNA replicons that only encode the RdRp, reproduce inside algal mitochondria or chloroplasts, and use the mitochondrial genetic code, thus resembling, in terms of both genome content and life style, mitoviruses of Branch 1. Evolution of this clade in Branch 2 might have followed a similar scenario as the evolution of ourmia-like viruses, namely, combination of an RdRp-encoding capsid-less genetic element inherited from prokaryotes with a capsid protein gene from a eukaryotic virus, in this case, a dsRNA virus.

Branch 3 in the RdRp tree encompasses about as much diversity of gene compositions and genome organizations as Branch 2 but only includes (+)RNA viruses. The branch contains two clades that consist of well-characterized viruses of plants and animals, some of these with large and highly complex genomes (by RNA virus standards), known as the “alpha-like supergroup” and the “flavi-like supergroup”, respectively (Fig. 3). The “alpha-like supergroup” encompasses an enormous range of viruses infecting plants and a smaller variety of animal viruses that share a signature block of VHGs encoding capping enzyme, superfamily 1 helicase, and RdRp. The conservation of this gene array testifies to the monophyly of the “alpha-like supergroup lineage”. The “flavi-like supergroup” is smaller and, until recently, included only the animal viruses of the family *Flaviviridae*. However, metaviromics studies have substantially expanded the group by adding a number of viruses with diverse genome organizations that infect either animals or plants. Similar to the “alpha-like supergroup” viruses, most of the viruses in the “flavi-like supergroup” encode helicases and capping enzymes but these belong to protein families distinct from those in the “alpha-like supergroup”, and clearly, have been acquired independently. Apart from the “alpha-like and flavi-like supergroups”, Branch 3 includes an assortment of lineages that all consist of short-genome viruses that encode only RdRp, CPs and, in some cases, one or two additional proteins. Two distinct, well-characterized clades in this assemblage are noda-like and tombus-like viruses but many more groups identified in metaviromes have joined the group.

Branch 4 in the RdRp tree consists entirely of dsRNA viruses. Similarly to the (+)RNA viruses from Branches 2 and 3, the dsRNA viruses in Branch 4 spread over a wide range of genomic length and complexity, from the minimalist genomes of totiviruses that encode only RdRp and CP to the highly complex reovirus genomes that consist of up to 12 genomic RNA segments containing numerous genes. The monophyly of the dsRNA viruses in this branch is supported by the conservation of the CP structure and capsid organization, with 60 homo- or heterodimers of the CP organized on a unique pseudo $T = 2$ lattice. The primitive toti-like viruses and the complex reo-like viruses form the two major clades within Branch 4. The reo-like clade also includes cystoviruses, the only known group of dsRNA viruses that infect prokaryotes. Thus, the pattern of apparent evolution of viruses of eukaryotes from prokaryotic ancestors that is observed in Branch 1 and, tentatively, in Branch 2 is recapitulated among the dsRNA viruses of Branch 4.

Branch 5 that includes all known (−)RNA viruses is the sister group of the reo-like clade within Branch 4. The monophyly of the (−)RNA virus RdRps is unequivocally supported by phylogenetic analysis, whereas the support for the position of the (−)RNA branch amidst the dsRNA viruses is weaker. However, this placement of (−)RNA viruses is compatible with the structural comparison of the (−)RNA virus and dsRNA virus RdRps. This tree topology perfectly fits the general logic of virus evolution: from the ubiquitous (at least, in eukaryotes) (+)RNA viruses to the less common dsRNA viruses, to the even rarer (−)RNA viruses. The dsRNA viruses and (−)RNA viruses share an essential aspect of the reproduction cycle, namely, packaging of the replication and transcription machineries into virus particles which allows virus reproduction in an infected cell to kick off by transcribing the virion RNA. This compartmentalization of the virus genomes was likely driven by selection for avoidance of the eukaryotic RNAi defense.

Branch 5 splits into two major clades, one of which includes, primarily, viruses with nonsegmented genomes that encode their own capping enzymes, whereas the other clade consists, mostly, of viruses with segmented genomes that use the mRNA “cap-snatching” mechanism (Fig. 3).

Reverse-Transcribing Viruses

Reverse-transcribing viruses are widespread and in many cases, highly abundant in animals, fungi, plants, and protists but, to the best of our current knowledge, are absent in bacteria and archaea. However, bacteria and archaea carry several classes of non-viral, capsid-less retroelements, such as group II introns, retrons and diversity-generating retroelements, whereas eukaryotes harbor several varieties of so-called non-LTR retrotransposons. Similarly to the RNA viruses, retroelements and reverse-transcribing viruses all share a single conserved gene that encodes the key replication enzyme of all these elements, RT. Thus, like the RdRp in the case of the RNA viruses, RT is the only phylogenetic marker for the evolutionary analysis of reverse-transcribing viruses. The phylogenetic tree of the RTs consists of 5 major branches, 4 of which include non-viral retroelements, and 5th, strongly supported branch encompasses all reverse-transcribing viruses. Thus, all reverse-transcribing viruses appear to be monophyletic, evolving from retrotransposons on a single occasion, most likely at the onset of eukaryotic evolution or shortly thereafter.

The virus branch of the RT tree consists of four clades, three of which correspond to the families *Hepadnaviridae*, *Pseudoviridae* and *Belpaoviridae*, whereas the fourth one unites 3 families: *Metaviridae*, *Caulimoviridae* and *Retroviridae*. The viruses in all these families, except for hepadnaviruses, share not only the RT but also two core components of the virions, the capsid and nucleocapsid proteins (the latter apparently lost in members of the *Spumaretrovirinae*, one of the retroviral subfamilies). Belpaoviruses, caulimoviruses, metaviruses, pseudoviruses, and retroviruses employ the same mechanism of replication priming, namely, utilization of host tRNA molecules as primers for reverse genome transcription. In contrast, hepadnaviruses use a protein-priming mechanism that is mediated by the terminal protein domain of the RT. Thus, it appears most likely that the five families of reverse-transcribing viruses are monophyletic, to the exclusion of *Hepadnaviridae*, apparently, the earliest branching family of reverse-transcribing viruses.

Viruses of the families *Hepadnaviridae* and *Caulimoviridae* (often collectively called “pararetroviruses”) that package dsDNA genomes into the virions and accordingly form Baltimore class VII are widely separated in the RT tree. Thus, Baltimore class VII is apparently polyphyletic, which makes class VI a paraphyletic group.

Single-stranded DNA viruses

The great majority of ssDNA viruses have small, circular genomes that replicate via the rolling circle mechanism. The ssDNA viruses infect a broad range of bacteria and some archaea as well as eukaryotes. Although these viruses have been missed in many early studies due to the miniscule size of their virions and genomes, metaviromics has shown that ssDNA viruses are diverse and abundant in various habitats and are a major component of the earth’s virome. The ssDNA viruses include 4 families of bacterial and archaeal viruses, *Inoviridae*, *Microviridae*, *Pleolipoviridae* and *Spiraviridae*, and 9 families of eukaryotic viruses: *Anelloviridae*, *Bacilladnaviridae*, *Bidnaviridae*, *Circoviridae*, *Geminiviridae*, *Genomoviridae*, *Nanoviridae*, *Parvoviridae* and *Smacoviridae*. Unusually, different members of the family *Pleolipoviridae* encapsidate either ssDNA or dsDNA genomes whereas parvoviruses and bidnaviruses have linear genomes. Whereas parvoviruses replicate via a rolling hairpin mechanism, a variant of the classical rolling circle, bidnaviruses encode their own protein-primed family B DNA polymerases.

The ssDNA viruses have “minimal” genomes which typically encode only a single replicative protein and a single structural protein, and in some cases, a few additional small, poorly characterized proteins. With the exception of anelloviruses, bidnaviruses, spiraviruses, and some inoviruses, the replicative protein of ssDNA viruses is the so-called HUH endonuclease that cuts genomic DNA at a specific site and initiates rolling circle (or rolling hairpin) replication. All eukaryotic ssDNA viruses that possess a HUH endonuclease also encode a S3H helicase that most often is fused to the endonuclease to form a two-domain Rep proteins. In contrast, ssDNA viruses of prokaryotes encode solitary HUH endonucleases. Apart from inoviruses, pleolipoviruses, spiraviruses, and the recently discovered FLiP virus that is expected to form a new family, ssDNA viruses have capsids made of SJR-MCPs.

Comparative analysis of the HUH endonucleases, S3Hs and CPs of ssDNA viruses points to multiple, chimeric origins of these viruses. The Rep proteins of eukaryotic ssDNA viruses appear to have evolved from homologous Rep proteins of small, rolling circle-replicating bacterial plasmids that also consist of HUH and S3H domains. Phylogenetic analysis of Rep proteins shows that viral replication machinery evolved from those of plasmids at least 3 times, independently. In parallel, HUH endonucleases of prokaryotic ssDNA viruses seem to have originated from plasmid endonucleases that are not fused to S3H. The CPs of most ssDNA viruses can be traced to a completely different source, namely, the SJR-CPs of different groups of plant and animal (+)RNA viruses. Thus, in a striking example of convergent evolution, ssDNA viruses apparently evolved on multiple, independent occasions via the same route, recombination between a bacterial plasmid and a cDNA copy of a (+)RNA virus.

The ssDNA viruses apparently gave rise to parvoviruses with their linear genomes and the rolling hairpin replication mechanism. Small dsDNA viruses with circular genomes, members of the families *Papillomaviridae* and *Polyomaviridae*, appear to have evolved from ssDNA viruses, most likely, parvoviruses, via a radical transition, inactivation of the HUH domain of the Rep protein that became a DNA-binding domain. Concomitantly, the replication mode of these viruses switched from the rolling circle mechanism to the bidirectional mechanism resembling plasmid and bacterial chromosome replication. The capsid proteins of small dsDNA viruses are highly derived, so it remains unclear whether these evolved from parvovirus CPs or were recruited independently.

Double-stranded DNA viruses

Double-stranded DNA viruses are the most diverse and expansive of Baltimore classes. These viruses dominate the prokaryotic virome and are common in eukaryotes as well, although not to the extent of the RNA viruses. No single gene is shared by all dsDNA viruses, thus, a phylogenetic tree for this Baltimore class cannot be constructed, even in principle. Nevertheless, networks of gene sharing, combined with phylogenies of the genes that are conserved in large virus groups, provide a working platform for classification of dsDNA viruses.

Broadly, the dsDNA virus gene-genome network splits into two large supermodules and three smaller modules. The supermodules are held together by distinct sets of genes that encode structural and morphogenic proteins, and each supermodule appears to be monophyletic, at least, with respect to the core genes.

The DJR-MCP supermodule includes numerous groups of viruses with icosahedral virions that infect bacteria, archaea and eukaryotes. In addition to the signature major capsid proteins, the majority of these viruses also encode SJR minor capsid proteins and genome-packaging ATPases of the FtsK-HerA superfamily. Apart from these 3 morphogenic genes, most of the viruses in this supermodule encode DNA polymerases and often additional components of the replication apparatus, such as S3Hs.

This supermodule includes the tail-less bacterial viruses currently classified in the families *Tectiviridae* and *Corticoviridae* and archaeal viruses in the family *Turriviridae*. Metavirome analyses reveal enormous diversity of unidentified members of this supermodule (one group forming the proposed family “*Autolykiviridae*”). Thus, the DJR-MCP viruses represent a major, perhaps even dominant, but so far poorly characterized component of the prokaryotic virome.

Eukaryotes harbor an even greater diversity of viruses of the DJR-MCP supermodule. Polintons (polintoviruses), virus-like self-synthesizing transposons, as well as diverse polinton-like viruses and virophages, appear to be direct descendants of bacterial tecti-like viruses. Adenoviruses are a derived form that evolved within the same line of descent. In addition to the two capsid proteins and the packaging ATPase, these viruses have acquired another gene for a protein involved in morphogenesis, a protease most likely derived from a deubiquitinating enzyme.

Nucleocytoplasmic large DNA viruses (NCLDV), a vast assemblage of several families of eukaryotic viruses (poxviruses, iridoviruses, phycodnaviruses, mimiviruses and more) with large or “giant” genomes (up to 2.5 Mb, in the case of Pandoraviruses) retain the DJR structural module including the protease, and thus, notwithstanding the striking genomic expansion, appear to have descended from polinton-like viruses. Tecti-like and polinton-like viruses, respectively, also gave rise to two groups of capsid-less elements, mitochondrial and cytoplasmic linear plasmids found in plants, fungi and some protists.

The HK97 supermodule unites the enormous variety of tailed bacterial viruses (bacteriophages), related viruses infecting archaea, and a single, albeit expansive group of animal viruses, the order *Herpesvirales*. The major capsid protein in the icosahedral capsids of these viruses is unrelated to DJR-MCP (the name of this supermodule comes from the name of a phage whose capsid was among the first determined capsid structures of this supermodule). In addition to the HK97-MCPs, viruses in this supermodule share portal proteins and the large and small subunits of the terminases, a distinct packaging ATPases that are not directly related to the packaging ATPases of the DJR-MCP supermodule viruses.

Apart from the structural and morphogenetic proteins, HK97 viruses have extremely diverse genome complexity and gene composition. Some of these viruses encode nearly complete replication machineries, whereas others virtually lack replication genes and rely on host replication apparatus entirely. The taxonomy of prokaryotic HK97 viruses, with the vast order *Caudovirales* classified into five families, *Ackermannviridae*, *Herelleviridae*, *Myoviridae*, *Podoviridae*, and *Siphoviridae*, is currently under reorganization and is likely to expand into many families in the near future.

A distinct, relatively small stand-alone module consists of several families of viruses infecting arthropods, such as baculoviruses and nudiviruses. These viruses have several genes that are distantly related to NCLDV core genes and thus could be peripheral members of the DJR-MCP supermodule.

A large module that is effectively disconnected from the rest of the network consists of viruses of hyperthermophilic Crenarchaeota which adopt diverse, unique virion structures, with capsid or nucleocapsid proteins unrelated to those of other viruses or to each other. Furthermore, most of these archaeal viruses lack genes encoding recognizable homologs for proteins of the replication apparatus encoded by other viruses. However, they are linked by shared genes for transcription regulators, glycosyl-transferases, and uncharacterized ATPases.

Finally, a stand-alone module in the dsDNA virus network includes papillomaviruses and polyomaviruses that evolved from ssDNA viruses, as discussed in the preceding section, and are unrelated to the rest of the dsDNA viruses. Notably, however, papilloma-polyomaviruses are linked to the DJR-MCP supermodule via an unusual group of dsDNA viruses, adomaviruses. These viruses combine a gene for a polyomavirus-like replication protein with genes for structural and morphogenetic proteins homologous to those encoded by adenoviruses. This is another, remarkable case of virus chimerism.

The Evolutionary Status of the Baltimore Classes, Global Organization of the Virus World and Higher Level Virus Taxonomy

Phylogenomic analyzes of all available groups of viruses outlined above place the Baltimore classes into an evolutionary framework (Fig. 4). Only one class, (–)RNA viruses, shows unequivocal evolutionary coherence as a monophyletic taxon. The dsRNA viruses are polyphyletic, with at least two major branches springing up from different parts of the (+)RNA virus tree. Accordingly, (+)RNA viruses, although, technically, monophyletic, represent a paraphyletic taxon with respect to both dsRNA viruses and –RNA viruses.

Among the reverse-transcribing viruses, the RNA-containing ones are paraphyletic with respect to one of the DNA-containing groups (caulimoviruses), whereas the second DNA-containing group (hepadnaviruses) forms a distinct branch. In addition to the splitting and mixing of Baltimore classes, the global organization of the virus world includes a grand unification of all RNA viruses with reverse-transcribing viruses, joining 5 Baltimore classes.

Baltimore Class II, ssDNA viruses, is a distinct case of chimerism and parallel recruitment of key genes from common pools of ancestors, which represents neither monophyly nor polyphyly, in the traditional sense. Furthermore, evolutionary analysis clearly indicates that small dsDNA viruses (polyoma-papillomaviruses) are derivatives of ssDNA viruses, once again demonstrating common origin of two Baltimore classes.

The dsDNA viruses present a clear-cut case of polyphyly of a Baltimore class, with at least 4 independent groups that do not share a common origin: the DJR-MCP and HK97 supermodules, crenarchaeal viruses, and polyoma-papillomaviruses. Thus, the Baltimore classes give a coherent and useful classification of viruses and correlate with the evolutionary relationships that are revealed through phylogenomic analysis. However, this correlation is far from perfect, so that, in general, the Baltimore classes are not monophyletic and, accordingly, cannot be taken as the highest-ranked taxa of viruses.

The Global Network Organization of the Virus World and the Key Events in Virus Evolution

Are there evolutionary connections that reach across the entire virus world? As discussed above, phylogenomic analyzes confidently indicate that some of the major groups of viruses do not share common ancestry, e.g., the 4 large groups of dsDNA viruses. However, this does not rule out the existence of connections. Indeed, strikingly, only 3 simple protein domains present in multiple VHGs, namely, RRM that forms the core of RNA and DNA polymerases, jelly roll, the core domain of SJR-MCP and DJR-MCP, and S3H, link the majority of the viruses in all Baltimore classes into a single network (Fig. 4). Thus, underneath the diverse evolutionary scenarios and the apparent polyphyly of viruses, lies a fundamental structural and evolutionary unity that, in all likelihood, goes back to very early stages of evolution.

Glossary

High throughput sequencing (HTS) New technologies capable of large scale nucleotide sequencing sequence assembly and analysis. The method has revolutionized the acquisition of virus sequence information, particularly from environmental samples.

International Committee for the Taxonomy of Viruses (ICTV) An international body with the task of developing

a single, universal taxonomic scheme for all viruses. The ICTV was created as a Committee of the Virology Division of the International Union of Microbiology Societies (IUMS).

Polythetic class A polythetic class is a group of like organism with common properties, although there may be no single property that is shared by all members assigned to that group.

Species in Biology

The primary category of living things is the species. For animals and plants, species correspond to a general division into organisms of single kinds, populations that share appearance and behaviors and importantly, can interbreed to produce offspring similar to their parents. The description of species as “Groups of actually or potentially interbreeding natural populations, which are reproductively isolated from other such groups” is the essence of the widely used biological species concept (BSC) developed by Mayr (see Mayr, 1942 in the Further Reading list). Species are also reproductively isolated from other species and collectively share an exclusive gene pool and a common evolutionary origin. They form a unit of selection that is subject to natural selection that underpins their adaptive fitness.

The application of the BSC is however severely limited by its reliance on inter-breeding ability as its primary inclusion criterion. There are many groups of organisms where this cannot be determined, for example, in the assignment of species to fossil forms and to parthenogenetic animals and plants, to bacteria and in the case of this article, to viruses. In these instances, there have been numerous proposals to define species based on morphology (morphospecies), population cohesion or connectedness, occupation of a specific ecological niche, and more recently by genetic relationships (cladistics or phylogenetic species) as genome sequencing becomes increasingly used for biological characterization. As many as 24–26 different species definitions have been recently reviewed, each with particular applications for particular groups of organisms (see the Mayden, 1997 review in the Further Reading list). The extension of species level classification into microbial and viral taxonomy has required further development of the species concept. What criteria might be used for viruses and the nature of the species thus created has been an immense challenge and area of controversy ever since the species level was first proposed around the time of the publication of the International Committee for the Taxonomy of Viruses (ICTV) 2nd Report in 1976. As described, these are far from being resolved.

Assignment of Viruses to Species

The Master Species List (MSL) maintained by the ICTV is the principal database of virus taxonomy information (see “Relevant Websites section”). Last updated in 2019, it lists a total of 4958 species of viruses, distributed into 846 genera and 143 families. These represent the primary (and obligatory) ranks used for any virus taxonomic assignment. Taxa form a set of hierarchical nested categories, so that one or more species (in the lowest rank classified by the ICTV) are members of a single genus, and one or more genera are assigned to a single virus family.

The Development of the Species Level in Virus Taxonomy

The motivation behind the original classification of viruses was to categorize the diseases that they caused. As infectious agents, viruses are responsible for a substantial proportion of human and veterinary morbidity and mortality, and of often devastating crop failures and other agricultural diseases of plants. The identification of viral causes was an important step in attempts to detect, contain and mitigate effects of infection and vaccinate against them. In the early era of virus discovery and characterization the 1950s and 1960s, the various morphologies, sizes of virus particles and presence of features such as envelopes, tails and spikes visualized by electron microscopy (EM) formed the original basis for family level classification, much of which is still in existence today.

Originally, however there was considerable reluctance to assign viruses in these virus families as species. It was unclear whether a division of viruses after the characteristics of the diseases they caused, as was done in microbiology, would be equivalent to the much more established traditions of species assignment elsewhere in biology. Milne and others furthermore argued that as viruses

were not living entities, and “best classified with other kinds of molecule or molecular complex” (Milne, 1988). They therefore could not form groups that would in any way correspond to animal or plant species. Secondly, without the possibility of applying the BSC to viruses, it was very unclear what level of difference between virus groups would be the equivalent of biologically-defined species elsewhere. Thirdly, it was not obvious whether specific traits used to identify virus groups, such as their disease associations or epidemiological distributions represented the same heritable traits on which species divisions of other organisms were based. A minor mutation within a species might dramatically affect the pathogenicity of a virus, while conversely viruses that caused the same disease, such as pneumonia or meningitis, might indeed belong to many species. Related to this, pre-genomics methods for virus comparisons, such as serological cross-reactivity or DNA hybridization methods were often highly discordant from virus groupings established by comparison of phenotypic properties. As previously noted by members of the ICTV in the late 1970s, many of the different flaviviruses assigned as different species because of their different disease outcomes showed extensive serological cross-reactivity. At the same time, different “types” of influenza A, assigned to a single species based on its disease associations, showed no serological cross-reactivity with each other.

Notwithstanding these identified problems, the first systematic attempts to classify viruses down to the level of species based on their observed properties started in the mid-1970s. These followed the pattern of yellow fever virus, assigned to the species “Yellow fever Flavivirus” (later reformulated as *Yellow fever virus*) in the genus *Flavivirus*, family *Togaviridae* (later re-assigned as *Flaviviridae*). Most early assignments of viruses matched disease, virus and species names together. In many ways, this descriptive approach to classify viruses corresponded to what biologists might do with animals, plants, fungi and bacteria – divide them up into entities that could be distinguished from each other, be it their symptoms, appearance of lesions, disease outcomes and fatality rates in humans or animals. Plant viruses may similarly induce a wide range of characteristic leaf, stem or root lesions, stunting and necrosis in particular host species that similarly provided a battery of descriptive names for the large number of viral crop diseases characterized at that time. Different viruses may additionally be characterized through their seasonality, geographical distributions and transmission by particular arthropod vectors.

Species Assignments and Genetic Relationships

Much of this early spadework in classifying viruses was done from the 1950s to the 1970s in an essentially pre-genomic age. Viruses could be isolated due to advances in sterile cell culture, they could be visualized by EM but could not be genetically characterized until the advent of large scale Sanger sequencing in the late 1970s. Through analyzing the sequences of cloned viral DNA sequences and, after that, of amplicons generated by polymerase chain reaction (PCR)-mediated genome amplification methods in the late 1980s, it became readily apparent that viruses classified in species, genera and families by phenotypic observations corresponded to genetically different lineages, and between different virus families, by major differences in genome organization and gene contents.

Sequence comparisons between viruses provides a much more fine-grained and objective metric of virus relatedness and, as elsewhere in biology, can contribute substantial additional classification information at multiple taxonomic levels. At one extreme it can identify and differentiate between individual virus strains or genotypes hitherto assigned to same species; at the other, it can provide evidence of distant homologies between replication-associated genes such as the RNA-dependent RNA polymerase. Their genetic relationships provide evidence for deeper evolutionary relationship between viruses that had previously been classified into separate families and orders. However, the advent of large scale genetic approaches for virus taxonomy opened up a Pandora’s box of problems for those involved in reconciling the newly derived genetic relationships between viruses with what was originally an largely phenotypically-grounded taxonomy. The relationship between sequence divergence and species assignment is particularly problematic and may never be reconciled.

Criteria Used in Species Definitions

The first formalised definition of a virus species was developed by Marc van Regenmortel and colleagues from the ICTV (Van Regenmortel *et al.*, 1991):

“A virus species is a polythetic class of viruses that constitute a replicating lineage and occupy a particular ecological niche”

This does not define what actual properties of a virus might be used to assign and differentiate between species, but at the time the definition was applied, these were typically based on descriptive features such as host range, antigenicity, epidemiology and distribution (“ecological niche”) rather than genetic relationships. The term polythetic has been used previously in descriptive biological species definitions and indicates that species may share a range of properties, but none of them are individually essential for species assignment. The further requirement that viruses assigned to a species are a single genetic lineage and an implied common ancestor distinct from all other viruses introduces a genomic-based element that was gradually adopted as sequence information became available in that period.

The species definition for viruses was revised by the ICTV in 2012 as follows:

“A virus species is a monophyletic group of viruses whose properties can be distinguished from those of other species by multiple criteria”

This revision remained as unclear as the original definition was about what “multiple” criteria might be used for species delineation. However, the removal of the term “polythetic”, widely believed by the ICTV to be misunderstood, also seemingly removed the need to include phenotypic information in a species description thus enabling viruses to be assigned largely or entirely by metrics of genetic relatedness.

The lack of defined criteria to assign species in both of the ICTV species definitions has undoubtedly contributed to the wide range of quite different descriptive elements and metrics of genetic relatedness used in species definitions in the ICTV taxonomy. This problem is exacerbated by a lack of coordinated oversight into how different viruses are classified and incorporated into the ICTV taxonomy. Most of the work in virus taxonomy is performed by a large number of separate Study Groups of virologists with expertise in particular families. While this division of labor has allowed those with the greatest knowledge of individual viruses and groups to be engaged in virus classification, the relative isolation of Study Groups and independence from each other has also led to the adoption of often quite different criteria for assigning species and genera to viruses they are classifying. A brief scan of the ICTV 9th Report reveals that species definitions for different families and genera vary between purely descriptive elements of virus disease, antigenic properties, haemagglutination or other properties of their isolates through to definitions that may be purely based upon sequence relationships. For the latter, the actual divergence thresholds and genome regions compared used for species divisions vary greatly between virus families. As examples, a <40% amino acid sequence identity of the RdRp divides partitiviruses into separate species while it is 50% in pseudoviruses (capsid gene), 60% in enterovirus species (structural genes) and 90% and 93% in bunyaviruses and hantaviruses (capsid gene). Nucleotide sequence identities might also be used, 30% in endornaviruses (complete genome [CG]), 40% in *Densovirinae* (non-structural [NS] gene), 65% in torquetenoviruses (ORF1), 70% in papillomaviruses (CG), 75% in nanoviruses (CG), 80% in caulimoviruses (*pol* gene), 89% in curtoviruses (CG) and 95% in parvoviruses (NS gene). Very clearly, what constitutes separate species in one virus family might be quite different for species in others.

Species definitions that are based on their clinical or agricultural disease associations furthermore frequently conflict with their underlying genetic relationships. There are currently 54 species assigned to the genus *Flavivirus* (family *Flaviviridae*), that like *Yellow fever virus* described above, bear names that simply derive from their component descriptively named viruses (e.g., dengue fever virus, tick borne encephalitis virus, West Nile virus etc.). Despite the fact that all species of flaviviruses were sequenced many years ago, their genetic relationships remain clearly subservient to their species assignments. There is consequently only a weak relationship between a flavivirus species assignment and its genetic divergence from other species. Two different species may differ by only 1.5% in nucleotide sequence, such as between *Israel turkey meningoencephalomyelitis virus* and *Bagaza virus*, but exceed 40% between others (*San Perlita virus* and *Ilheus virus*). Different types of dengue fever virus assigned to the same species *Dengue fever virus* show greater than 32% nucleotide sequence divergence from each other but these distances that are substantially greater than those between most other flavivirus species. Other anomalies include the assignment of *Louping ill virus* as a separate species from *Tick-borne encephalitis virus* on the basis of its distinct geographical distribution in the UK and different host range, even though phylogenetically, variants assigned to this species lie entirely within the much more diverse viruses assigned to *Tick-borne encephalitis virus*.

In the case of flaviviruses, there seems to be little enthusiasm in the *Flaviviridae* Study Group to reassign species to better match underlying genetic sequence relationships. However, conflicts of this sort elsewhere in the virus taxonomy have led to major reorganizations underlying genetic relationships are revealed. For example, there have been repeated instances of clinically similar viruses having to be re-assigned to different species or even genera or families once their sequences were determined; echovirus 22 and 23 were moved from the genus *Enterovirus* into a new genus, *Parechovirus* in the family *Picornaviridae*. Even more radically, whole families have been split and member species and genera reassigned. As a typical example, the original family *Togaviridae* was divided into *Togaviridae* and *Flaviviridae* when major differences in genome organization and a lack of sequence homology between genes became apparent. The species *Rubella virus* in the genus *Rubivirus* was then subsequently also removed from the *Togaviridae* and assigned to a new family *Matonaviridae* once its lack of genetic relatedness to members of this originally assigned family was acknowledged. Several similar re-organisations of the existing taxonomy are likely in the near future.

Species and Genotypes

While there remains a historical legacy of descriptive species assignments in some families despite their often wildly different genetic relationships, the classification of newly characterized viruses into species is increasingly based on metrics of genetic relatedness. However, this may create the converse problem of poorly matching assignments with medically or biologically relevant properties that virologists and clinicians might want to use for classifying them. For example, all variants of hepatitis E virus (HEV) have, perhaps unhelpfully, been placed into a single species, *Hepevirus A*, along with a range of other HEV-like viruses infecting other mammalian species. (The other species, *Hepevirus B*, *C* and *D*, incorporate even more divergent virus groups with similarly variable host associations.) Because members of *Hepevirus A* were already highly divergent in sequence from each other (30% amino acid sequence divergence in conserved domains of methyltransferase, helicase and polymerase genes), much of the medically relevant classification activity revolves around the assignment of genotypes and subtypes within the species. For example, HEV types 1, 2, 3 and 4 infecting humans possess quite distinct geographical ranges, routes of transmission and risk group associations, properties that might at one time have led to their assignment as different species.

Members of the *Hepacivirus* genus in *Flaviviridae* are a similar case in point; the human hepatitis C virus (HCV) is assigned to the one species *Hepacivirus C* (14) even though the clinically and epidemiologically relevant differentiation is at the level of genotype and subtype within this genus. The sequence divergence between HCV genotypes (>30%) is indeed greater than those between different species in its sister *Pestivirus* genus, such as *Pestivirus A* and *Pestivirus B*. As a further example in another virus family

(*Picornaviridae*), a small proportion of poliovirus infections are associated with a severe neurological outcome, poliomyelitis, that quite distinct from the disease associations of all other enteroviruses. Originally assigned to the species *Poliovirus*, the more recently developed 40% amino acid sequence divergence threshold in the structural gene block now used to delineate enterovirus species places them as just three serotypes among a much larger group of other enteroviruses assigned to the species, *Enterovirus C* that lack these disease associations. As a contrast to this “lumping” effect, species assignments based on lower divergent thresholds may atomize existing virus groups for little apparent purpose. In a much discussed example highlighted by Marc van Regenmortel (2016) (see Further Reading list), the application of an 9% divergence threshold to begomoviruses created over 300 genomically defined species, including the split of the species *Tomato leaf curl virus* into 42 species without any clear or consistent biological relevance.

Overall, these examples and many others demonstrate that species of viruses may not be the lowest element in classification and there may be a considerable degree of variability between virus families and even genera about what constitutes a species and what constitutes a genotype, sub-type or even strain.

Classification of Metagenomically Characterized Viruses

This development of purely genomics-based species assignments has become particularly relevant for the classification of viruses identified and assembled from datasets generated by high throughput sequencing (HTS). The application of such methods to environmental samples and rarely investigated hosts such as insects and other arthropods has revealed a staggeringly diverse sets of new and unfamiliar genetically diverse viruses. These show a degree of genetic and genome organizational diversity that warrants the ongoing and future creation of potentially hundreds of new virus families to accommodate them.

Although some properties of the metagenomically-derived viruses might be inferred from their genome organization and gene complements, as well as their sampling locations and in many cases, inferences about their likely hosts, their classification have to be essentially based on genetic relationships. Many virologists have forcefully and cogently argued against this policy (van Regenmortel *et al.*, 2019). However, the ICTV, supported by the conclusions of an expert group convened to specifically to discuss this issue (Simmonds *et al.*, 2017), has proceeded to assign such “sequence-only” viruses to the official taxonomy equivalent to those already assigned. This policy requires decisions to be made on family-, genus- and species-level assignments in the frequent absence of any phenotypic or other descriptive support. The incorporation of sequence-only viruses had greatly expanded the ICTV taxonomy and will undoubtedly continue to do so as virus characterization in metagenomic datasets proceed.

Emergence of a Genomics-Based Taxonomy of Viruses

The previous section outlines the transitions from an original phenotypically-driven assignment of viruses to species to a new framework that is primarily based upon virus genetic relationships. The current taxonomy is an uncomfortable mix of species defined by these different methods, with large discrepancies in both the nature of the species groups formed, but also in the motivation behind and utility of the species entities that are created (Table 1). The utilitarian assignment of viruses based on phenotype properties creates categories that are immediately of clinical or other biological value (left column), produce informative names and yet often fail to reproduce the underlying genetic relationships of the viruses so classified, nor can they be readily applied for species assignments of sequence-only viruses from metagenomic datasets. Contrastingly, genomics based species assignments (right column) are consistent with virus evolutionary relationships on which a taxonomy ultimately has to be based, and yet for many virologists it fails in its primary purpose in providing relevant categories for applied research. Species may lack descriptive elements that link viruses to their observable properties, their definitions may be based on arbitrary and often misplaced assignment thresholds that may atomize existing species or create varied and inconsistent distinctions between species and genotypes. Thresholds or other metrics of genetic relatedness furthermore produce no obvious basis for species names which are frequently numerically or alphabetically coded.

Table 1 Features of phenotypic and genomics-based species assignments

Phenotypic assignment	Genomics-based assignment
Provides a biologically and clinically relevant division of viruses	Assignments approximate to evolutionary relationships between and within species
Species names are typically descriptive and informative	Species names are often serially numbered without any indication of virus properties
Variable association with genetic divergence between and within species members	Species may contain viruses with different biological or clinical attributes
Assignments may conflict with evolutionary relationships	Sequence divergence threshold used species differentiation are variable between virus groups and often arbitrary
Cannot be applied to viruses without information of biological properties (eg., those derived from metagenomic datasets)	Can be readily applied to viruses with both known and unknown (eg., from metagenomic data) phenotypes

As the taxonomy expansion develops, an increasing proportion of species will be genomically defined, with an increasingly small “rump” of the originally descriptively classified species remaining. Reconciling these legacy assignments with the expanding genomics framework awaits future organizational initiatives by the ICTV.

Species Nomenclature

The principles behind naming virus species has undergone several revisions and the current nomenclature is far from being consistent or logical as a result; it may also change substantially in the future. As described above, naming is influenced by the underlying principles used to delineate species, be it based on descriptive properties or genetic relationships. Historically, the initial reluctance of virologists to assign species extended to and fueled a parallel resistance to adopt the Linnaean binomial nomenclature that is used elsewhere in biology for virus species. After the initial classification of viruses into families and genera was better established in the mid-1970s (5), many of the component viruses within these, ultimately to be defined as species, were informally named using a non-Latinized binomial of the form <virus name> + genus, *e.g.*, West Nile flavivirus (the reverse of the Linnaean genus + species principle). In 1998, the ICTV implemented a formal nomenclature for assigned species as a non-Latinized (usually English) monomial (*i.e.*, species only) name that was based typically on the name of the virus within the species. In contrast to Latinized binomials, there is no specific format for virus species names. Those derived from descriptive species definitions were often formed from two to four word epithets matching the virus name (*e.g.*, *Dengue virus*, *Banana bunchy top virus*). Species names may, however, additionally include numeric or alphabetic identifiers or combinations (*e.g.*, *Enterovirus A*, *Homalodisca coagulata virus-1*, *Torque teno mini virus 12*), that often arise from species defined genomically where a descriptive name may not be obviously relevant.

Although typographically marked by italicization and capitalization, the frequent identity of the names of the virus and the species to which it is assigned (*e.g.*, yellow fever virus is a member of the species *Yellow fever virus*) creates confusion and has engendered frequent misuse of virus and species terms in the literature. The ICTV is currently (in 2019) conducting a community-wide consultation on the advisability of applying a Linnaean nomenclature scheme to virus species; it would more effectively mark species names in text, their Latinized epithets would better differentiate species names from virus names, names would be more informative through inclusion of the genus assignment and finally their use would engender compatibility with the nomenclature used in the rest of biology, including microbiology.

What are Species?

The ICTV maintains a strict division between the identity of a virus and the identity of the taxon to which it is assigned. Under current guidance, a species (or a genus or other taxonomic rank) is strictly defined as a class or category into which viruses, as real world entities are assigned. Thus, poliovirus type 3 is member of the species *Enterovirus C*. Polioviruses possess specific replication and morphological properties and have effects on the cells that they infect and specific disease associations. Contrastingly, *Enterovirus C* as a class or a category does not replicate, has no morphology, no effect on cells and no pathogenicity. This relationship formalizes the requirement for separate names for viruses and taxa, the former representing the “common” name for a virus, which may indeed be different in different languages (rabies virus and virus de la Rage are both members of the species *Rabies lyssavirus*) and the latter representing the name assigned by the ICTV to the taxon.

However, this strict differentiation between organism and the taxon to which it is assigned is widely misunderstood and the names of species and other taxonomic ranks are often conflated in the literature with the viruses they represent. In part, this may originate from a much less clear and often implicit rather than defined differentiation of organisms and taxa in the terminology used in microbiology and elsewhere in biology. For example, an individual may be infected with *Escherichia coli* or by *Streptococcus pyogenes* (implicitly by the bacteria assigned to these species), but he or she cannot be infected by *Enterovirus C*, only by poliovirus, coxsackie virus A21 or one of the many other enteroviruses assigned to that species. It seems unlikely that the ICTV will conform to usage elsewhere in biology in this respect so this potential source of confusion will potentially continue even if a Latinized binomial nomenclature is ultimately adopted.

Summary

While biologists know pragmatically what species are, and have little difficulty in assigning animals, plants, fungi and other organisms to them, formal definitions of species differ considerably in their applicability to different groups of organisms. The plethora of currently used species concepts and definitions underpins much of the ongoing difficulty and uncertainties in how to classify viruses at this taxonomic level. Variants of what might correspond to morphological or phenetic species definitions that classified viruses based on their observed clinical or epidemiological properties have largely given way to a version of the evolutionary species concept, based on virus genetic relationships as the features available for species characterization have changed. The current virus taxonomy is an unresolved composite of different classification methods and further complicated through quite inconsistent metrics of genetic relatedness used to assign species in different virus families and genera. The currently

used formal definition of a virus species contains elements of both phenotypic and genetic characteristics that does not clearly delineate which are necessary or sufficient for species assignments. Species are named by italicized, capitalized monomial names often corresponding the virus name in English, quite different from the Latinized binomial nomenclature used elsewhere in biology. The consequently frequent close resemblance of virus and species names to each other despite a rigidly enforced typological distinction between a species and a member of a species has led to the frequent misuse species terms for viruses. In the future, this may be resolved, at in part, through the adoption of Latinized binomial names that are consistent with their use elsewhere in biology.

Glossary

Basic reproductive number Average number of new infections generated by an infected host.

Clonal interference Failure of beneficial alleles to get fixed in a population due to the presence of other, more beneficial alleles.

Defective interfering virus Mutant lacking a portion of the viral genome that replicates at the expense of and interferes with functional viruses.

Error catastrophe Process whereby, at high mutation rates, lower-fitness mutants become more abundant than higher-fitness variants.

Fitness Production of viable progeny, usually averaged over individuals of a given genotype and expressed relative to a reference genotype.

Fitness landscape A representation of the genotype-fitness map.

Genetic complementation Compensation of a genetic defect by the presence of other, functional copies of the mutated gene in the same cell.

Genetic hitch-hiking Increase in the population frequency of a deleterious mutation driven by genetic linkage with a beneficial mutation.

Lethal mutagenesis Demographical extinction of a population due to mutation accumulation.

Muller's ratchet Irreversible accumulation of deleterious mutations in a population as a result of random genetic drift.

Mutation rate Probability that a new genetic variant is produced per generation, where a viral generation is often defined as the completion of a cellular infection cycle.

Mutation-selection balance Equilibrium between the influx of new deleterious mutations in a population and the removal of these mutations through selection.

Selection coefficient Difference between the fitness value of a genetic variant and the fitness value of a reference genotype.

Viral quasispecies A population of viruses replicating and competing at high mutation rates.

Introduction

Viruses exhibit highly heterogeneous genome structures and replication strategies. These basic features correlate with viral propensity to mutate and, hence, with viral genetic diversity and evolvability. The mutation rates of viruses vary according to genome composition (RNA or DNA), size, and structure (single- or double-stranded). In general, RNA viruses produce from 10^{-6} to 10^{-4} new base substitutions per nucleotide per cell, whereas these rates range from 10^{-8} to 10^{-6} in DNA viruses (Fig. 1). Furthermore, single-stranded viruses appear to mutate faster than double-stranded viruses, and an inverse correlation between genome size and mutation rate has also been demonstrated. Within the DNA virus group, thus, single-stranded viruses and, presumably, some double-stranded viruses with small genomes, mutate faster than double-stranded viruses with large genomes.

The term quasispecies has been used to refer to highly heterogeneous viral populations in which the frequency of mutations in the population is determined by mutation rate and fitness. The quasispecies concept has thus been applied mainly to RNA viruses, owing to their particularly high mutation rates. High population genetic diversity is believed to play a pivotal role in the ability of RNA viruses to adapt to changing selective pressures and invade new hosts. Indeed, RNA viruses comprise a large number of well-known human emerging or re-emerging pathogens such as HIV-1, hepatitis C virus, influenza virus, Ebola virus, and Zika virus among many others, as well as major plant and animal pathogens. In contrast, DNA viruses are typically less diverse and evolve more slowly, although they also include important pathogens such as herpesviruses and poxviruses. Nevertheless, the divide between RNA and DNA viruses is imperfect, since some RNA viruses evolve slowly and some DNA viruses are fast-evolving, particularly single-stranded and small double-stranded DNA viruses.

This article focuses on the sources of genetic diversity in viruses and on the resulting evolutionary processes at the population level (we do not review long-term viral evolution at the phylogenetic level). The main mechanisms responsible for introducing new mutations are discussed, including replication errors, lack of proofreading, repair avoidance, diversity-generating elements, host-encoded editing of viral genomes, and recombination (Table 1). We review how population diversity is modified by natural selection and genetic drift, and how this leads to different evolutionary processes in viruses. Finally, we discuss some practical implications of viral diversity for pathogenesis, immune escape, and drug resistance.

Fig. 1 Mutation rates in different types of viruses. Estimates obtained for viruses belonging to the major indicated groups are shown as a function of genome size. This reveals an effect of genetic material (RNA/DNA) and genome size on viral mutation rates. Data taken from Sanjuán, R., Domingo-Calap, P., 2016. Mechanisms of viral mutation. *Cellular and Molecular Life Sciences* 73, 4433–4448. doi:10.1007/s00018-016-2299-6.

Error-Prone Replication

Intrinsic Selectivity of Viral Polymerases

The fidelity of a polymerase is first determined by its selectivity towards the correct base. Such selectivity is typically on the order of 10^4 – 10^5 , and there appear to be no major differences among RNA-dependent RNA polymerases, reverse transcriptases (RTs), and DNA polymerases. Polymerase variants with altered selectivity and fidelity have been reported in a wide variety of RNA viruses. Serial transfers in the presence of the base analog ribavirin were first shown to select for an increased-fidelity polymerase in polioviruses. Ever since, tens of fidelity mutants have been identified amongst widely different RNA virus families. The evolution of high- and low-fidelity variants in response to selective pressures such as chemically-induced mutagenesis demonstrates that selection can optimize RNA virus replication fidelity. However, most RNA virus fidelity variants show only modest differences in base selectivity compared to the wild type, revealing strong structural or biochemical constraints. Interestingly, the fidelity of viral DNA polymerases appears to be less constrained.

Other Factors Determining Polymerase Selectivity

In addition to the intrinsic fidelity of a polymerase, the rate of base misincorporations depends on factors such as sequence context, divalent cation concentrations, and the relative abundance of dNTPs. For instance, polymerase slippage occurs frequently in homopolymeric templates, producing insertions and deletions. In hepatitis C virus, mutation rates can vary extensively between consecutive bases in the viral genome, suggesting a major role for sequence context in determining replication fidelity. RNA secondary structure can also determine the rate at which replication errors occur.

Lack of Proofreading

Polymerases displaying 3' exonuclease activity can correct most nucleotide misincorporations. However, this activity is generally absent from RNA virus polymerases. Currently, only coronavirus RNA polymerases have been shown to perform

3' exonuclease proofreading. Lack of proofreading is a major factor responsible for the higher rates of spontaneous mutation of RNA viruses compared to DNA viruses. Because RTs also lack 3' exonuclease activity, retroviruses and pararetroviruses mutate at rates similar to those of most RNA viruses. Although DNA virus replicases exhibit 3' exonuclease activity, certain amino acid replacements in their polymerases inactivate proofreading and produce a strong mutator phenotype, as shown for instance in bacteriophage T4. Interestingly, there are also amino acid replacements in the T4 polymerase that increase fidelity up to a hundred-fold compared to the wild type. Finally, polyomaviruses, which use host polymerases for replication, can encode proteins that inactivate the 3' exonuclease proofreading domain of the host polymerase. Therefore, avoidance of proofreading may also be a mechanism whereby some DNA viruses increase their population diversity.

Role of Post-Replicative Repair

Repair Avoidance

Post-replicative repair is a highly efficient system for removing replication errors and repairing DNA damage. As such, lack of repair can increase mutation rates strongly. RNA viruses are not substrates of cellular repair systems, whereas some DNA viruses have evolved specific features to avoid repair. This is the case of bacteriophage Φ X174 and potentially other small DNA phages. In *Escherichia coli*, strand-specific mismatch repair uses the methylation status of GATC sequence motifs to discern between the parental and daughter DNA strands. Interestingly, the Φ X174 genome is devoid of GATC motifs. This prevents methylation and thus, post-replicative repair, allowing the phage to increase its mutation rate relative to that of the host. Eukaryotic viruses might also avoid repair or dysregulate repair pathways to increase their mutation rates, although this has not been investigated in detail.

Error-Prone Repair Polymerases

Eukaryotic viruses are known to interact with DNA damage response pathways. For instance, some small DNA viruses activate these pathways to prolong the S cell-cycle phase and promote their replication. DNA damage response pathways comprise error-prone DNA polymerases for re-synthesis of excised strands, which might contribute to elevating viral mutation rates. On the other hand, some large DNA viruses encode their own DNA repair system. For instance, African swine fever virus encodes an endonuclease, a repair polymerase (pol X) and an ATP-dependent DNA ligase. Pol X is highly error-prone due to a poor base selectivity and lack of 3' exonuclease activity. Use of pol X might contribute to the relatively high genetic diversity shown by African swine fever virus isolates.

Diversity-Generating Retroelements

First described in a *Bordetella* phage, diversity-generating retroelements are genetic cassettes found in different bacteria, plasmids, and DNA bacteriophages. They contain two short repeated sequences, called the template and the variable repeats. The template repeat is transcribed and then reverse-transcribed by an RT encoded by the cassette. During this process, adenines are systematically substituted for random bases. The resulting cDNA is integrated, replacing the former variable repeat with a new, highly mutagenized sequence. This process allows hyper-mutation of specific phage genes involved in host attachment, a trait that is often subject to rapidly changing selective pressures.

Viral Hyper-Mutation Mediated by Host Enzymes

Cellular Cytidine Deaminases

Apolipoprotein B mRNA editing catalytic polypeptide-like enzymes (APOBECs) function as an innate immune response against reverse-transcribing viruses. APOBECs are cytidine deaminases that massively introduce C-to-U base substitutions in the retroviral cDNA, leading to a characteristic G-to-A hyper-mutation pattern in retroviral genomes. It has been estimated that 98% of new HIV-1 mutations are produced by APOBECs, versus only 2% caused by HIV-1 RT errors. Hyper-mutation produces non-infectious genomes, which accumulate as inactive proviruses. In cases of moderate mutation, though, APOBECs might contribute to viral evolution and could even promote immune escape and drug resistance. In addition to retroviruses, APOBECs can edit hepatitis B virus as well as other non-reverse transcribing DNA viruses such as papillomaviruses, herpesviruses, and human polyomaviruses.

Cellular Adenosine Deaminases

Double-stranded RNA-dependent adenosine deaminases (ADARs) constitute another type of host-encoded enzymes capable of editing and hyper-mutating RNA virus genomes. ADARs deaminate adenosines in long double-stranded RNA regions, converting them into inosines, which leads to A-to-G base substitutions. ADAR-induced hyper-mutation was first discovered in measles virus and was then extended to other viruses including human parainfluenza virus, respiratory syncytial virus, lymphocytic choriomeningitis virus, Rift Valley fever virus, influenza virus, noroviruses, and Zika virus, although in many cases evidence for ADAR-mediated mutagenesis is still indirect.

Recombination

Recombination plays an important role in viral evolution. Similar to mutation rates, recombination rates vary extensively among viruses. High rates of recombination may have been favored by natural selection to promote the fixation of new genotypes, to purge deleterious mutations, or as a by-product of other evolutionary processes. For recombination to introduce new genetic variants, it is required that the involved genomes differ by at least two mutations. Furthermore, the recombining molecules have to be present in the same cell. Hence, the emergence of new variants through recombination typically occurs in cells infected with different pre-existing variants. However, this may not happen frequently because super-infection exclusion renders infected cells refractory to re-infection with the same or a related virus. On the other hand, even if rare, recombination between distantly related viruses has the ability to introduce major genetic changes in a single event, such as gene transfer, leading to the emergence of new viral subtypes or even new species. Hence, recombination differs from mutation in the type and abundance of the genetic changes produced.

Reassortment

In segmented and multicomponent viruses, recombination is greatly facilitated by the possibility of re-assorting genome segments. However, barriers to reassortment also exist. For instance, co-packaging of a given genome segment with the segments of another virus requires that their packaging signals are compatible. Reassortment has been extensively studied in influenza virus, for which inter-subtype reassortments between swine, avian and/or human influenza A viruses are known to be at the origin of several pandemics. Reassortment between viruses of the same subtype can also be an important source of diversity, can promote adaptation, and can accelerate immune escape. Reassortment also plays a major role in the evolution of other viruses such as rotaviruses, favoring the emergence of new variants and complicating vaccination efforts.

Template Switching

Even if reassortment is not possible, recombination can still take place through a template-switching mechanism whereby the viral polymerase and the nascent chain dissociate from one template and associate with another. The rate at which this template-switching process occurs has been measured experimentally using genetic markers, and typically ranges from 10^{-5} to 10^{-3} events per nucleotide site per co-infected cell in different retroviruses such as HIV-1, murine leukemia virus, and spleen necrosis virus, as well as in positive-stranded RNA viruses such as mouse hepatitis virus, poliovirus, and tobacco etch virus. Whereas the production of new variants through template switching also requires that the cell is coinfecting with two different variants, in retroviruses such as HIV coinfection with two independent virions is not required because virions are diploid. In contrast to retroviruses and positive-stranded RNA viruses, most negative-stranded RNA viruses show very low rates of template switching. Similar to replication fidelity variants, viral polymerases with different propensities to template switching have been isolated. Such variants have allowed investigating the evolutionary implications of recombination from an experimental evolution approach using poliovirus. This has suggested that recombination increases the ability to purge deleterious mutations from the population and promotes the spread of beneficial mutations. This may accelerate adaptation and increase viral pathogenicity.

Recombination in DNA Viruses

Recombination is a more complex process in DNA viruses than in RNA viruses and involves specific host or viral recombinases. DNA virus homology-dependent recombination can be mediated by cellular double-stranded break repair systems. These systems act on double-stranded DNA viruses but also on single-stranded DNA viruses because the latter produce double-stranded replicative intermediates. Some DNA viruses encode their own recombination systems. For instance, phage λ recombination is active in cells deficient for the *E. coli* recombinase RecA. Also, the herpesviruses recombination machinery plays a major role during viral replication and repair. There is ample evidence that this type of recombination is sequence-dependent. For instance, the inverted terminal repeats of the vaccinia virus genome undergo rapid changes in size because this region contains multiple 10–100 bp repeats that are highly prone to unequal crossovers. Some viruses can use recombinogenic sequence motifs for targeting diversity towards certain genes. In poxviruses, this allows for a recombina-

Fig. 2 Genetic, demographical, and ecological processes determining viral population diversity. Mutation is the ultimate source of genetic variation, but recombination also produces new genotypes. Ecological and demographical processes determine how natural selection and random genetic drift acts on these new genetic variants. This leads to a variety of possible population genetic processes, which in turn feedback on viral demography, ecology and genetics. Immune escape, drug resistance, and pathogenesis are a visible consequence of such processes. The list of factors shown is not exhaustive.

tion-mediated gene amplification process that can temporarily increase the dosage of viral genes involved in evading host innate immunity.

Basic Population Genetic Processes Shaping Viral Diversity

The fate of new genetic variants is largely determined by selection. The population frequency of a new mutant will tend to increase, fluctuate randomly, or decrease depending on whether it has a beneficial, neutral, or deleterious effect on viral fitness, respectively. Yet, the fitness of a given allele is context-dependent in several ways, since it varies according to genotype-genotype and genotype-environment interactions. To a large extent, the environment of a virus is dictated by the host, but it can also be modulated by other members of the viral population via competition for cellular resources or cooperative interactions. Allele frequencies can also change as a result of random genetic drift. Drift is determined by the effective size of the viral population, which in turn depends on spatial structure, population size bottlenecks during host-to-host transmission, viral growth dynamics, and so on. Therefore, both selection and drift are conditioned by multiple demographical and ecological factors, which results in a variety of population genetic processes (Fig. 2). Below, we briefly summarize some of these processes.

Mutation-Selection Balance

Since natural populations tend to be adapted to their environments, most new mutations with a fitness effect are deleterious and, hence, selection tends to remove them from the population. When the influx of genetic diversity produced by mutation equals the outflow due to selection, the population reaches an equilibrium called the mutation-selection balance. In haploid populations, the population frequency of a given deleterious allele at the mutation-selection balance simply equals μ/s , where μ is the mutation rate and s the selection coefficient. The selection coefficient ranges from zero for neutral alleles to one for lethal alleles. The time for this equilibrium to be reached depends inversely on s , the equilibrium being reached instantaneously (in one generation) for $s = 1$. In RNA viruses, the statistical distribution of selection coefficients for new mutations has been characterized using site-directed mutagenesis. This has revealed that RNA viruses show very high s -values (on average, $s > 0.1$) compared to other microorganisms. Hence, selection against deleterious mutations acts strongly on RNA viruses. This implies that the mutation-selection balance tends to be reached in few generations and that, at equilibrium, most genetic variants have low population frequencies. Supporting this view, high-fidelity Illumina sequencing of experimental poliovirus populations has revealed a large number of deleterious variants at frequencies that are not detectable by conventional next-generation sequencing. A likely explanation for why s -values are high in RNA viruses is that their genomes are extremely compact, with few and often multifunctional and overlapping genes, many of which

are essential. These genome features also apply to small DNA viruses and, consequently, mean s -values are also very high for DNA viruses such as microviruses (e.g., phage Φ X174) and inoviruses (e.g., phage M13).

Viral Quasispecies

Quasispecies theory is primarily a theory of mutation-selection balance at extremely high mutation rates. Quasispecies were originally studied within the framework of physical chemistry as models for the dynamics of self-replicating sequences in a hypothetical primitive RNA world. However, due to the high mutation rates exhibited by RNA viruses, the theory subsequently became popular amongst virologists. Despite using different terminology, quasispecies and classical mutation-selection models essentially deal with the same process and are largely equivalent. Yet, quasispecies models make a more explicit approach to mutant dynamics by explicitly considering the replicative rate of each sequence as well as the probability of each sequence mutating to another specific sequence. A transition matrix is thus defined, whose eigenvector with the highest eigenvalue defines a stable mutation-selection balance. This approach defines fitness as a property of the ensemble of sequences present at equilibrium (the quasispecies). As a consequence, fitness is not merely determined by the initial sequence, but also by its mutational neighborhood. This means that a quasispecies containing a maximally fit individual sequence might be outcompeted by another quasispecies that does not contain the fittest sequence but shows higher average fitness. This phenomenon is called the survival of the flattest. A related prediction of quasispecies models is that, beyond a certain mutation rate, the fittest sequence within a given quasispecies can be outnumbered by its own cloud of deleterious mutants, a process known as error catastrophe. How this process occurs depends on the topology of the fitness landscape. Original quasispecies models assumed a landscape with a single high-fitness sequence (master) in which all mutants had the same fitness value. In this particular system, beyond the error threshold all mutants reach a frequency similar to that of the master and, since there is an extremely large number of such possible mutants, the actual frequency of the master sequence becomes vanishingly small.

Error Catastrophe and Lethal Mutagenesis of Viruses

The theory of error catastrophe suggested that viral populations could be effectively extinguished by increasing the viral mutation rate sufficiently. Treatment of RNA virus experimental populations with chemical mutagens has provided ample support for the feasibility of mutation-driven extinction in cell cultures and even in animal models. However, error catastrophe models only deal with the fitness of certain sequences relative to others, and thus ignore the fact that extinction is an absolute, demographical process that takes place when the basic reproductive number of a population decays below one. It has been thus suggested that extinction of experimental RNA populations following mutagen treatments is better defined as lethal mutagenesis process. Regardless of the models used and the mechanisms underlying extinction, empirical evidence strongly support the view that RNA viruses naturally exist at the verge of mutation-driven extinction, since extinction can be induced by modest increases in mutation frequencies. In contrast, the lower rates of spontaneous mutation shown by most DNA viruses makes them less likely to undergo lethal mutagenesis or error catastrophe.

Adaptation via Directional Selection of Beneficial Mutations

The high mutation rates exhibited by RNA viruses reduce the waiting times required for the emergence of selectively beneficial mutations compared to other microorganisms. The emergence of beneficial mutations is also favored by the extremely high population sizes of RNA viruses, which is on the order of billions of infectious particles per infected host. For a mutation rate of 10^{-5} substitutions per nucleotide per round of genome copying, replication of a population of 10^9 viral particles should produce as many as 10^4 mutations, which approaches the total number of possible single-point mutations in a typical 10 kb RNA virus genome. This makes RNA viruses extremely responsive to host adaptive immunity, antiviral drugs, and other rapidly-changing selective pressures. Yet, despite favoring the appearance of beneficial alleles, high mutation rates can hamper their fixation process in the population. First, at high mutation rates, many genomes carry several deleterious mutations, and beneficial mutations may fail to be selected if they occur in low-fitness genetic backgrounds. Alternatively, if the beneficial effect of a mutation exceeds the disadvantageous effect of other mutations present in the same genome, deleterious mutations can undergo fixation, a process known as genetic hitch-hiking. Another “traffic issue” in fast-mutating systems is clonal interference, a process whereby multiple beneficial mutations coexist in the same population and only the fittest variant is selected, leading to extinction of other beneficial variants. Since lower mutation rates increase waiting times for the emergence of beneficial mutations but higher mutation rates reduce the efficiency with which beneficial mutations are selected, adaptation should be maximal for some intermediate, optimal mutation rate. A similar optimality argument can be used for neutral evolution. Analysis of empirical data suggests that RNA viruses replicate at nearly-optimum mutation rates. Lastly, clonal interference, counter-selection of beneficial alleles in low-fitness genetic backgrounds and hitch-hiking can all be dissipated by recombination, since recombination can break disadvantageous genetic combinations and create new ones.

Frequency-Dependent Selection

The fitness of a given virus can be modified by other viruses of the same population. Such interactions can be cooperative or competitive, and are more likely to occur among viruses infecting the same cell because this allows them to share proteins. Coinfection of a cell with independent virions requires a high local density of viral particles. However, many viruses spread as collective infectious units composed of multiple particles, which promotes coinfection even at low overall viral densities. When a situation in which each cell receives multiple viral particles is maintained for several infection cycles, defective viruses tend to invade the population. Defective viruses, produced by illegitimate recombination, lack large portions of the genome and can only replicate as hyper-parasites at the expense of complete viral genomes present in the same cell. In addition to replicating faster than the wild type because their genomes are shorter, defective viruses often interfere with some steps of the infectious cycle. Hence, the fitness values of both the wild type and the defective viruses are frequency-dependent. Viral interference can produce sharp drops in fitness, which has led to suggest defective interfering viruses as possible antivirals. The emergence of interfering viruses can also be promoted by chemically induced mutagenesis in RNA viruses. On the other hand, coinfection of cells with different virus variants may allow for cooperative virus-virus interactions. In principle, two viruses each carrying a different genetic defect can mutually increase their fitness values if they share gene products (genetic complementation). It is also possible that each variant has optimized a different aspect of the infection cycle, and that such variants achieve higher fitness in coinfection than alone. This type of cooperative interaction has been suggested for measles virus and influenza virus, and might contribute to the maintenance of viral genetic diversity because fitness would be maximal at intermediate frequencies of each variant in the population. Therefore, diversity can lead to negative or positive virus-virus interactions. In turn, these interactions feedback on diversity by modifying the population frequency of certain variants.

Random Genetic Drift

Despite their enormous population sizes, viruses experience significant genetic drift. This is because the strength of drift depends on the effective population size, not on the census size. Demographical bottlenecks have a strong and long-lasting effect on effective population sizes, and such bottlenecks occur extensively during inter-host transmission in nearly all viruses. The size of the founder population following inter-host transmission has been estimated using genetic markers, and is typically lower than 10 genome copies. This number, though, can vary widely depending on transmission route (aerosol, fecal-oral, sexual, insect-borne, etc.). Additionally, viral infections show extensive intra-host spatial structure caused by restrictions to viral trafficking among tissues or organs (organ compartmentalization) as well as by the limited diffusion of virions in the extracellular milieu (localized infection foci). Spatial structure also reduces effective population sizes, hence promoting drift. The immediate consequence of drift is the loss of genetic diversity, because only a subset of the population contributes to the next generation. A longer-term consequence is the random fixation of alleles in the population. In highly variable populations such as those of RNA viruses and at sufficiently low population sizes, drift can result in the loss of the wild-type sequence. In the absence of back mutation or recombination, this loss is irreversible and hence leads to the accumulation of random mutations in the population, most of which are neutral or deleterious. This process, known as Muller's ratchet, reduces mean population fitness and can endanger the survival of small RNA virus populations.

Implications for Viral Disease

Viral population genetic diversity plays a major role in the ability of viruses to cause disease. In general, pathogens evolve faster than their hosts owing to their shorter generation times and higher population sizes. In addition, in their evolutionary arms race against hosts, most viruses benefit from a faster mutation rate, particularly RNA viruses. On the other hand, hosts have the ability to deploy complex antiviral responses such as adaptive immunity. As a result, viruses are subject to continual selective pressure for avoiding antiviral defenses.

Short-Term Pathogenesis

Different early processes including efficient entry, local replication, and rapid spread determine pathogenesis. The association between RNA virus population diversity and pathogenesis has been examined using polymerase fidelity variants. Increased-fidelity variants are typically attenuated in animal models, suggesting a role for viral population diversity in causing disease. This was first shown using a variant of poliovirus carrying a single amino acid replacement in the polymerase that confers an approximately three-fold increase in replication fidelity. Since these experiments involved acute infections, adaptive immunity was probably not responsible for the observed association between population diversity and pathogenesis, and the mechanism linking intra-host viral diversity with pathogenesis has not been elucidated. Importantly, low-fidelity variants have also been tested and found to be attenuated. A candidate alternative explanation for these results is that in RNA viruses, high mutation rates have been selected as a byproduct of selection for high replicative speed. Increasing fidelity would come at the cost of slower growth, hence producing an attenuated phenotype. On the other hand, decreasing fidelity further would elevate the mutational load of the population, reducing mean population fitness at mutation-selection balance or promoting error catastrophe.

Immune Escape

In chronic infections such as those caused by HIV or hepatitis B and C, among others, adaptive immune responses involving neutralizing antibodies and cytotoxic T cells select for escape mutants during the course of infection. In HIV-1, the ability of the virus to escape immunity partially correlates with its ability to generate a genetically diverse intra-host population. DNA viruses such as, for instance, herpes simplex virus also cause chronic infections and, hence, have to cope with the adaptive immune response as well. Yet, their strategy for evading immune responses appears to be based on latency rather than on the continual production of immune escape variants. In viruses causing acute infections, adaptive immunity escape mutants are also selected, but this process occurs mainly at the inter-host population level. For this selection to occur, hosts need to recover from infection. This creates a host subpopulation immunized against the virus variant that originally infected them, thus favoring escape variants. This process has been amply documented for influenza virus, and is called antigenic drift or antigenic shift, depending on the diversity-generating process at play. Antigenic drift is mainly based on point mutations that change epitope sequences, whereas antigenic shift occurs as a result of segment reassortments that produce new subtype combinations. Finally, immune escape is not restricted to vertebrate viruses. For instance, bacteria use clustered regularly interspaced short palindromic repeats (CRISPR) and associated proteins as an adaptive immune system. Bacteriophages can escape CRISPR via point mutations and have also evolved anti-CRISPR proteins (Acrs) of variable strength.

Drug Resistance

Antiviral drugs impose a strong selective pressure on viruses causing chronic diseases such as HIV-1. The first attempts to treat AIDS using base analogs failed due to the emergence of drug-resistant mutants. Monotherapies were subsequently replaced with combination therapies aimed at preventing drug resistance, which have been successful despite the remarkable genetic variability of HIV-1 intra-host populations. A similar scenario applies to hepatitis C virus, in which resistance against protease inhibitor-based monotherapies emerges rapidly through one or few mutations, thus requiring the use of combination therapies. Targeting different steps of the viral infection cycle, such as for instance nucleoside analog-based polymerase inhibitors and protease inhibitors reduces the risk of resistance compared to combination therapies aiming at a single target. An alternative antiviral treatment consists in taking advantage of the highly error-prone replication of RNA viruses to promote viral extinction via lethal mutagenesis using nucleoside analogs or other mutagenic compounds. This type of treatment can select for high-fidelity polymerases that partially compensate the mutagenic effect of the drugs, although this might not be sufficient for preventing viral extinction. In other cases, drug-resistance against mutagenesis may fail to evolve. Finally, yet another alternative treatment strategy that has been designed to minimize the evolution of drug resistance consists in targeting host factors such as molecular chaperones, the viral receptor, or proteins involved in the immune response.

Conclusions

Viruses are a highly heterogeneous group of molecular parasites showing varied replication strategies, genome organizations, mutability, and evolutionary properties. RNA viruses are characterized by their elevated mutation rates and extremely high genetic diversity, but reverse-transcribing DNA viruses, single-stranded DNA viruses, and some small double-stranded DNA viruses can also achieve high levels of population genetic diversity. Here, we have shown how viral diversity is generated by widely different molecular mechanisms, including lack of proofreading, avoidance of DNA repair, host-mediated viral genome editing, and specific diversity-generating modules, as well as different mechanisms of recombination. However, viral diversity does not only depend on these purely genetic factors. Ecological and demographic processes determine the action of natural selection and random genetic drift, producing a myriad of different population genetic processes, of which pathogenesis, immune escape, and drug resistance are observable consequences. Therefore, viral population diversity and evolution should help us develop more efficient antiviral control and treatment strategies.

Glossary

Evolvability The potential for a biological entity (such as an RNA virus) to create new, beneficial phenotypes, typically through rapid genetic adaptation. RNA viruses are often considered very evolvable because their high mutation rates create many different genomes that can have different phenotypes, a small number of which may be beneficial.

Fitness The ability of a genotype to produce descendants (grandchildren and beyond) in a particular environment.

Genomic architecture The structure of a genome, which can involve its nucleic acid, whether it is single- or double-stranded, whether or not it is segmented or has a single genomic molecule, gene content and order and secondary structures that form in the genome.

Genotype The set of alleles carried in an individual.

Homologous Adjective describing similarity between two items due to common descent. Used here in the context of homologous sequences, which would be similar or identical regions of two or more RNA viral genomes.

Life history The sequence of events relevant to survival and reproduction from birth to death. Life history traits of viruses including adsorption rate, lysis time, and burst size, have a direct bearing on fitness and have been observed to vary widely. Since resources are not unlimited, life histories strategies are often constrained by trade-offs, for instance, increases in fitness of one trait decrease the fitness of another trait.

Nonsynonymous A genetic mutation that leads to a change in amino acid, which causes a change to the encoded protein. For example a uracil-to-cytosine mutation, causing a codon to change from guu to gcu, changes a valine into an alanine.

Phenotype The physical manifestation of the genotype in a particular environment. It is the set of observable

characteristics, which are influenced by the genotype, the environment, and any interactions between genotype and environment.

Phylogeny A representation of the evolutionary relationships among lineages, such as isolates of a viral species descended from a common ancestor. Evolution leads to branching patterns as lineages diverge. Viral phylogenies are based on genomic similarity, which can be used to infer evolutionary history of a lineage. Phylogenies are useful in molecular epidemiology of outbreaks.

Reassortment A form of genetic exchange that occurs in RNA viruses when multiple segmented viruses co-infect the same host cell; the progeny virion can package a mix of the parental segments into a single progeny virion.

Recombination A form of genetic exchange that occurs in RNA viruses when the RdRp falls off of one template and reattaches to another template.

RNA-dependent RNA polymerase (RdRp) The enzyme all RNA viruses have that complements a single-stranded RNA genomic segment for replication and to produce transcripts.

Secondary structure Regular structures formed by the primary sequence of a macromolecule, in this case the RNA genome, which folds into hydrogen bonded stems with regions of unpaired loops.

Substitution rate The rate at which mutations come to very high frequency (ideally present in 100% of individuals) in a population or a lineage, typically measured in years.

Synonymous A “silent” genetic mutation that does not lead to a change in amino acid, preserving the encoded protein. For example a uracil-to-cytosine mutation, causing a codon to change from guu to guc, does not change the amino acid – both call for valine.

RNA viruses have a well-deserved reputation for fast evolution compared to DNA-based life, and most DNA viruses. They are known to have very high mutation rates, change and adapt quickly, are linked to the bulk of host-shifting zoonotic diseases and often confound human abilities to make durable vaccines. However, while RNA viruses may make use of strategies that many other viruses and cells do not, they evolve according the same principles that govern the rest of nature; evolution occurs through mutation, recombination (including the migration of alleles from other lineages into a viral genome), selection and drift. The fact that RNA viruses show different evolutionary patterns than DNA organisms comes from a combination of their genetics, life history and environmental factors. In addition, not all RNA viruses employ the same strategies and evolve in the same way or at the same rate: there is tremendous diversity among RNA viruses.

RNA Viruses Have High Mutation Rates

Evolution is fueled by mutations – changes to genomes that occur during genomic replication and at other times. They make up the bulk of the variation upon which natural selection and drift (see below) acts. These mutations can change the proteins coded by a virus, the regulation of a gene, affect a secondary structure important for function, or may not have any effect on the phenotype of the virus at all. Since any virus capable of successful infection has sufficient fitness, most mutations decrease fitness, harming the virus that carries them.

Fig. 1 RNA viruses with rigorously measured mutation rates (per base, per infection), plotted by their genome size. Mutation rates from positive sense ssRNA viruses (bacteriophage Qbeta, human rhinovirus 14, poliovirus 1 and tobacco mosaic virus, hepatitis C virus, tobacco etch virus, murine hepatitis virus) are shown as red diamonds, negative sense ssRNA viruses, (vesicular stomatitis virus, influenza A virus and influenza B virus) are shown as blue triangles and the sole measured mutation rate from a dsRNA virus (bacteriophage phi6) is shown as a yellow square. Data are from Rafael Sanjuán's viral mutation rate compendium (see relevant web pages, below).

Some mutations do not have much of an effect on the phenotype (are neutral or nearly neutral), and a small fraction of mutations are beneficial. Even though most mutations are not beneficial, biological entities like viruses with short generation times and many offspring per infection can sample a lot of mutations and stumble across beneficial mutations faster than cellular organisms.

Much of that ability to sample many mutations in a short period of time is due to RNA viruses having high mutation rates. All RNA viruses have higher mutation rates than their hosts – a hundred to a million times higher. However, not all RNA viruses have the same mutation rate. Viruses with single-stranded genomes have faster mutation rates than the sole double-stranded RNA virus with a measured mutation rate (bacteriophage phi6, 2×10^{-6} mutations/base/infection). The mutation rates of RNA viruses are thought to be as high as they possibly can be without creating too many mutations per generation to maintain the information encoded in their genomes. Too many mutations lead to a build-up of deleterious mutations, dramatically reducing fitness and even resulting in a critical and irreversible loss of genomic information. Viruses of roughly similar genome sizes have mutation rates that vary by almost 1000-fold, which means that there is no common, or optimal mutation rate for all RNA viruses (Fig. 1). One of the main reasons RNA viruses have such high mutation rates is the RdRps that all RNA viruses use to replicate their genomes typically lacks any ability to proofread and correct errors during replication. Exceptions to this are larger RNA viruses (family *Nidovirales*), which have an RdRp that is phylogenetically distinct from the RdRp shared by most RNA viruses, which have genomes ≤ 20 kb. These larger RNA viruses (up to ~ 41 kb) have a unique part of their RdRps which has the ability to cut out nucleotides from the newly synthesized RNA. This proofreading reduces the mutation rate compared to just the polymerization of the RdRp, and permitted genome sizes of these viruses to grow up to double the size of those RNA viruses without it (note the data point from murine hepatitis virus, a member of *Nidovirales*, which has the largest genome size of all viruses in Fig. 1).

One of the reasons RNA viruses have such high mutation rates is because more careful polymerization takes time, and faster replication is inherently sloppier replication. All else being equal, a virus with faster replication, and therefore a higher mutation rate, can have more offspring in the same time as a virus with slower replication, and therefore a lower mutation rate. Or the faster replicating virus can burst its cell earlier and its offspring will have an advantage finding their next host cell compared to the slower replicating virus. More of the offspring of the faster and sloppier replicating virus may have mutations that inactivate the virus, or reduce its fitness, but some of their offspring will be successful. Overall, this has been a more successful strategy for RNA viruses than a slower and more careful replication speed.

The mutation rate of RNA viruses is evolvable, but mostly in the direction of a lower mutation rate – higher mutation rates are not tolerated well, which is one of the reasons scientists feel RNA virus mutation rates are quite close to the highest they possibly can be. In the laboratory, some RNA viruses have evolved lower RdRp mutation rates. Multiple groups who have passaged poliovirus in the presence of a mutagen to increase the extrinsic mutation rate have evolved a more fidelitous RdRp, which has a G64S mutation in its polymerase. When scientists have used mutagens to increase RNA virus mutation rates, the increasing number of mutations per genome causes the viruses to poorly replicate and make few viable offspring, eventually killing the population. This lethal mutagenesis is one of the ways some of the drugs clinically used against RNA viruses and retroviruses can work. Ribavirin is an antiviral that is an RNA base analog that can be incorporated into RNA viral genomes and complements both uracil or cytosine, increasing the virus' mutation rate.

In addition to mutagens like ribavirin, many hosts make enzymes that can increase the mutation rate of RNA viruses. The best studied of these is the cytidine deaminase APOBEC3G that is part of the innate antiviral defense of some mammals, including humans. This enzyme targets cytosines in viral genomes, both the DNA form of retroviruses and hepatitis B and the RNA genomes of viruses such as measles, mumps and respiratory syncytial virus. These enzymes can turn many cytosines into uracils on a single viral genome, and its effect was termed "hypermutation" when discovered in the early days of HIV sequencing. Host cells also make adenine deaminases (ADAR) that have been observed editing the bases of RNA viruses, including vesicular stomatitis virus (VSV) and measles. Both of these mechanisms are thought to be the cell using an increased mutation rate as a way of inactivating RNA viruses – encouraging lethal mutagenesis.

Finally, just as RNA viruses themselves have a wide range of mutation rates, varying over more than 100-fold, mutation rates and frequencies of RNA viruses vary even within a single species. Host environment is an important factor for mutation, with plant viruses like cucumber mosaic virus having different numbers (and kinds) of mutations depending on whether it infects a pepper or tobacco plant. The same effect has been seen in the arbovirus VSV, which infects both mosquitos and mammals: VSV has a lower mutation rate in insect cells than in mammalian cell culture. Understanding how and why hosts influence the mutation rate of their invading viruses is an open area of research, but a similar effect has been seen in long-term viral substitution rates. Scientists measure mutation rate as numbers of mutations per base, per round of genomic replication or per infected cell. However, they measure genomic evolution in numbers of very high frequency mutations (ideally present in all members of a population), per base, per year or other unit of time. RNA viruses with different mutation rates often have similar rates of evolution through time, and scientists have endeavored to find out why some RNA viruses do evolve faster than others. A meta-analysis showed that the sole determinant of faster evolution in mammalian RNA viruses was primarily infecting epithelial cells – and slower evolution was associated with infecting neural cells. There may be a relationship between the replicative ability of the host cells and evolutionary rate – epithelial cells divide the fastest of all mammalian tissues, and neurons the slowest – but this is another example of host cells influencing RNA virus evolvability.

Genetic Exchange

The ultimate source of most novel genetic variation is mutation, but genetic exchange through recombination and reassortment brings together different variants to make potentially novel genotypes. Additionally, there is the potential for recombination to make novel alleles of genes not yet generated by viral mutation, such as when viruses recombine with homologous sequences in transgenic plants. Recombination occurs when a viral genomic segment has more than one parental sequence; reassortment occurs when different genomic segments in a segmented or multipartite virus have different parents. Both kinds of viral gene exchange have the potential to create progeny with much higher levels of variation than a single generation of replication with the virus' error-prone RdRp alone. However, gene exchange need not create novel variation – identical viruses can undergo the processes of recombination and reassortment and produce the identical offspring to the parents (Fig. 2).

Recombination

While most people are familiar with recombination as the reciprocal gene exchange that occurs in diploid, sexually reproducing eukaryotes, viruses do not undergo reciprocal gene exchange. Instead, as is the case throughout the microbial world, one viral genome is the donor to another, which is the acceptor. In RNA viruses, recombination is usually homologous, meaning that the sequences of the donor and acceptor parent strains are very similar at the site of recombination, which usually leaves the structure and protein-coding capacity of the recombination genome unchanged (Fig. 2). Recombination can also be non-homologous (illegitimate), which includes both unrelated viruses without homologous regions recombining, or the site at which related viruses are recombining is not one of high sequence similarity. Such non-homologous recombination is usually deleterious, which is perhaps why it is observed less frequently than the homologous type. Recombination between viruses always occurs during co-infection of the same cell by multiple viruses. Very rarely viral RNA can recombine with host RNA, but recombination with host genetic material is much more common among DNA viruses.

Copy-choice is the most widely accepted mechanism for RNA viral recombination and is also termed replicative recombination. Originally described in poliovirus, recombination occurs when the RNA polymerase falls off the donor template and reattaches to an acceptor template – thus switching which parent it copies from for the offspring sequence – during genome replication. The site at which the polymerase switches templates is called the breakpoint, and homologous recombination is encouraged by the partially

Fig. 2 Forms of genetic exchange among RNA viruses. During co-infection, multiple parental genomes can be replicated simultaneously, and offspring virions package with a combination of the parental genomes. (A) Recombination produces offspring that have a genome segment that is a hybrid of the parental genomes. Here, we depict homologous recombination. (B) Reassortment produces offspring that have a combination of genome segments from the parental genomes.

sequenced offspring genome (or genomic segment) complementarily pairing to the new template. The RdRp binds to the new template, continuing to synthesize the progeny RNA, creating a chimera of the parental templates. Sequence similarity between the templates at the breakpoint can encourage recombination, helping reduce the probability of non-homologous recombination, which is more likely to produce deleterious genotypes. The kinetics of replication and the secondary structure of RNA may also influence the likelihood of switching templates, such as when a part of the genome is covered in nucleoproteins and is less accessible for replication. Secondary structures are also known to create hotspots of RNA virus recombination.

There are other mechanisms of non-replicative recombination that follow a breakage-joining model, where genetic fragments from different viruses join to form hybrid genomes. As breaks can theoretically occur anywhere in the genome, the mechanism can be either homologous or non-homologous, but it is more likely to be non-homologous given that it can occur randomly. Although non-replicative recombination *in vivo* is possible, it has only been observed in cell-free laboratory settings and it is not known what, if any, contribution non-replicative recombination makes in nature.

Reassortment

Reassortment is another form of genetic exchange that can occur in segmented viruses—viruses that have their genome split into multiple segments. Reassortment only occurs when multiple viruses co-infect the same cell, and replicate their progeny segments in the same cytoplasm. The progeny virions are assembled from a mix of segments from the parental virions, creating a novel assortment of genome segments – a hybrid – into a capsid (Fig. 2). In most segmented viruses, such as those from the families *Cystoviridae*, *Orthomyxoviridae*, and *Reoviridae*, segments usually neatly replace each other, so each progeny virion gets a single copy of each segment. Unlike recombination, which can occur nearly anywhere in the genome, creating chimeric genomic segments, reassortment swaps entire genes or sets of genes with no chance of disturbing gene coding. In multipartite viruses – viruses for which each genome segment is packaged in a separate virion – reassortment is stochastic, with segments from parents resulting in infection events with a random mix of segments. Interestingly, reassortment in multipartite viruses need not occur in infected cells, or even when multiple viruses coinfect the same multicellular host; it can also occur during vector transmission. Also, segmented and multipartite viruses can also undergo both reassortment and recombination, *e.g.*, rotavirus, influenza A, hantavirus, flock house virus, and plant viruses, although one form of genetic exchange may be more frequent than the other depending on the virus.

Even though the exact details of how reassortment occurs across viruses differ, some generalizations about the process can be made. After the genome segments have been replicated, packaging signals indicate how the genome segments should be incorporated into the viral capsid, regardless from which parent the segments are derived. Although the parental virions may differ, the packaging signals need to be compatible enough for the segments to assemble in a single virion. The exact mechanisms of reassortment vary among different viral families. The process of reassortment is well understood in the bacteriophage $\phi 6$ (*Cystoviridae*), which is described here as an example. This phage has a genome divided into three segments, each of which is individually inserted into the procapsid in sequence. Encapsidation of each segment triggers a conformational change, revealing the binding site specific for the next segment to be packaged. Once encapsidation is complete, the procapsid expands, triggering the segments to synthesize the negative-sense strand of their dsRNA genome and completing virion morphogenesis. The poster child for a frequently reassorting virus would be Influenza A, which has eight genomic segments. Its reassortants are closely watched by public health researchers because successful, human-infecting reassortants can lead to epidemics and the failure of that year's flu shots, which were designed based on influenza evolution in the absence of reassortment.

Rates of Recombination

Recombination and reassortment rates vary across viruses, but nearly all viruses recombine, and segmented and multipartite viruses are all thought to reassort. Some families show higher rates than others, *e.g.*, (–)ssRNA viruses tend to have low rates of recombination, and (monopartite) segmented viruses tend to exhibit lower levels of recombination. On the other hand, multipartite viruses have been observed to have higher recombination rates in addition to exchanging genes *via* reassortment. Furthermore, recombination rates vary according to environmental factors. Since recombination between different viral strains requires that the host cell be co-infected by those strains simultaneously, factors that influence the incidence of co-infection, *e.g.*, virion particle density in the environment surrounding the host cell, can influence how often recombination occurs. Reassortment rates among the family *Cystoviridae* have been observed to vary markedly by geographic location.

Detecting Recombination

All recombination detection methods look for similarity between regions of related genomes, and then identify disruptions in the pattern of the relationships between regions. This can be achieved by comparing phylogenetic trees that have been constructed for different components on a set of virus genomes, though not all methods require phylogenetic incongruence. The incongruences between phylogenetic trees can be visualized using tanglegrams (Fig. 3). A link to a Windows-native freeware program that unites many recombination detection methods together in one graphic interface is given in relevant web links (below).

Fig. 3 A cartoon example of a tanglegram, a way of visualizing phylogenetic incongruence, which can provide insights into genetic exchange between different viral groups. The left and right phylogenies represent two different genes in a viral species. The colored lines connect the two genes from the same individual virus. Because the phylogenies are not identical, the colored lines sometimes cross each other, which is an indication of gene exchange. The two genes do not have an identical evolutionary history in this virus.

Evolutionary Outcomes for Recombination and Reassortment

Like mutation, most gene exchanges are not thought to be beneficial, even when the recombination is homologous. However, there are many well-studied examples of the rare beneficial outcomes of gene exchange, where recombination led to host range expansion, transmission *via* new vectors, increases in virulence and pathogenesis, evasion of host immunity, antiviral resistance, or the ability to infect new tissue types. Like winning the lottery, hybrid offspring may receive a highly beneficial mix of their parental genomes and also be in an environment where this genetic combination allows them to have a selective advantage. One of the best-described examples of this is in the Western equine encephalomyelitis (WEE) complex of viruses, an alphavirus that formed as the result of a recombination event between Eastern equine encephalomyelitis virus (EEEV) and Sindbis-like viruses that probably occurred within the last 2000 years. This recombination event led to the evolution of a predominantly EEEV-like virus that inherited a capsid from its Sindbis-like ancestor. Similarly, reassortment can confer great fitness advantages, such as when reassortment among circulating strains of influenza has repeatedly led to competitively superior strains of influenza A. Several instances of strains endemic to swine or birds have been able to jump into humans after a reassortment event, *e.g.*, the 1957 'Asian', 1968 'Hong Kong', and 2009 'swine flu' pandemics. The first two pandemics were the result of reassortment between a circulating human and avian strains, while the latter pandemic arose from multiple reassortment events between highly divergent North American and Eurasian swine, avian, and human strains. Such cross-species reassortment events have often been observed in concert with the emergence of pandemic strains of influenza. The introduction of alleles to a different influenza strain is a form of migration, which is rarely discussed in virology as separate from recombination and reassortment.

In addition to hybrids, recombination and reassortment can also generate defective interfering particles – a type of social cheater that can only replicate in the presence of another virion that can supply the missing functions. These particles can usually tolerate large deletions while maintaining crucial genes for replication and packaging but rely on the co-infecting virus to supply those missing functions. These cheaters benefit disproportionately from this relationship, gaining an intracellular fitness advantage due to their small size and fast replication while interfering with the replication of the co-infecting virus.

Natural Selection in Viruses

After a population of RNA viruses has generated genetic diversity through mutation and recombination, the varied viral genotypes in the population will be subjected to selection. If a viral genotype makes a phenotype with a fitness advantage – an advantage over other viral genotypes in the population – then it will leave more offspring, and over time its descendants will increase in frequency in the population. Otherwise, if the phenotype has a lower fitness level, that genotype will likely be pruned from the population over time. The fitness of an individual is its survival and reproductive success relative to the rest of the population. Evolution by natural selection occurs in all biological entities, and is an inevitable consequence of the three following conditions: (1) variation in phenotypic traits must exist, (2) the phenotypic variation must correlate with genetic variation, and (3) individuals with these different traits have differential reproduction. For instance, imagine there is variation within a population of viruses in how a virus attaches to a receptor on the surface of a cell. The variation for attachment has an underlying genetic basis, *i.e.*, different genotypes attach differently. The genotypes that attach more securely are able to produce more progeny virions and be proportionally more numerous in the next generation, and therefore are of higher fitness. Which genotypes are most fit in a population is a function of a large number of biotic and abiotic factors, and the same population of viruses would have different genotypes positively selected in different environments.

Three common kinds of effects of natural selection can be discussed in terms of the interactions of viruses and host immune systems: positive (adaptation), purifying, and diversifying (or disruptive) selection (**Fig. 4**). Positive selection is directional – phenotypes of increasing extremes of a trait are selected as genotypes at the other end of the distribution of the trait leave fewer and fewer offspring. One example of this is the CpG content of Influenza A genomes since the host-shift of this virus into humans from

Fig. 4 Forms of selection and how they impact the distribution of trait values. The dashed line indicates the distribution prior to selection. The solid line shows the distribution after selection has acted on the population. The arrows indicate which portion of the trait values were selected against. (A) Positive selection acts against trait values from one extreme, resulting in a distribution shift away from that extreme. (B) Purifying selection acts against trait values from both extremes of the distribution, resulting in a narrower yet higher peak. (C) Diversifying selection acts against the mean of the distribution, favoring extreme trait values. In this single-axis example, it results in a bimodal distribution of trait values.

birds in the early 1900s. Mammals, but not birds, recognize cytosines next to guanines in RNA (CpG sites) as a sign of foreign genes in the cell, which triggers an innate immune reaction. Influenza A strains that first encountered humans in the 1918 pandemic had many CpG sites, and one theory of why the pandemic killed healthy adults more often than the young and old is that healthy adults mounted a huge immune response to these genomes, resulting in frequently fatal cytokine storms. Over the last century, the CpG content of circulating flu strains has steadily decreased – evidence of selection against high CpG strains and for lower CpG strains in a directional manner.

While positive selection is the most intensively studied of the kinds of selection discussed here, purifying selection is the most common kind of pressure on viruses (and all biological entities). Since most mutations and gene exchange events hurt fitness, most phenotype-affecting mutations will cause their genotypes to leave fewer and fewer offspring over time, and the affected genotypes will drop out of the population. This is the strong selection to maintain the exact function of all the proteins in a virus by maintaining the exact protein sequences. Purifying selection is exemplified by arboviruses that use an insect vector between mammalian hosts. The exterior proteins of arboviruses, such as the capsid proteins, are under stronger purifying selection and must maintain their exact protein sequences more than related viruses that do not use vectors. This is because the coat proteins must be functional in two very different animal cell types – and mutations have a very high probability of disrupting fitness in at least one of the hosts.

Diversifying selection also plays a significant role in viral evolution. Mammalian immune systems recognize viral epitopes and develop antibodies to neutralize these viruses upon further encounters (or in the case of vaccine-induced immunity, upon first encounter). For instance, after a flu season, most people are immune to the most prevalent flu strain's epitope, and that exact strain will not re-infect those who have already developed antibodies to it. However, any differences in the epitope, even slight ones, may allow a virus to break that immunity. Variants are more successful than the most prevalent strain of the prior year – natural selection favors strains that are different, but not in a particular, directional way.

The most common way to detect whether a gene is under selection is d_N/d_S : the ratio of the rate of nonsynonymous changes to the rate of synonymous changes. More nonsynonymous mutations persisting over time means that changes to the protein were not deleterious, possibly even beneficial. A high d_N/d_S ratio indicates positive or diversifying selection. A higher rate of synonymous substitution means that changes to the protein were deleterious and quickly removed from the population, which indicates purifying selection – changes to the protein sequence of the gene do not survive long in the population. Sometimes virologists will find a d_N/d_S ratio near unity, indicating that both nonsynonymous and synonymous mutations are equally likely to survive, which often means that the region is evolving neutrally and is not a gene that is under selection to maintain function. A popular website that can calculate d_N/d_S from aligned datasets is given in relevant web links (below).

Coevolution With Hosts

Hosts and their viruses can exert intense selective pressure on each other. Viral infections may lead to high fitness costs or death for the host, while the viruses depend on their hosts for reproduction. RNA viruses evolve quickly, and there are endless examples of viruses evolving to better exploit their hosts. Recent human genomics research suggests defending against viral infection has been very important for human evolution over longer stretches of evolutionary time, with RNA viruses Hepatitis C and Influenza among the 10 viruses having had the greatest impact on human genetic variation. Coevolution occurs when both the virus evolves in response to the host and the host evolves in response to the virus, for instance creating an arms race of successive rounds of selection for beneficial mutations for more virulent viruses and well as stronger defenses in the host. Coevolution does not require the number of evolutionary changes to be equal, as fast-evolving RNA viruses are expected to respond to selection on hosts more and more often than slower evolving hosts can. Reciprocal cycles of coevolution of RNA viruses and mammals are difficult to observe experimentally, given the hosts' slow generation time, but have been seen through experimental evolution: in the laboratory, and in the release of rabbit hemorrhagic disease virus as a biocontrol agent for rabbits in Australia.

On the other hand, coevolution can be detected through inferential methods. Mutually beneficial relationships between viruses and hosts imply a long-term interaction that was honed through rounds of natural selection. One example would be the

dependence of a tropical panic grass on a dsRNA virus-infected fungus, which allows the grass to grow at high soil temperatures, far above what the plant can grow alone or even with the uninfected fungus. When the fungus was cleared of the viral infection, the plants died, indicating a clear evolutionary advantage to maintaining viral infection.

More commonly, scientists take a computational approach to discern long-term relationships between viruses and hosts that could indicate coevolution. It is clear that primates and the closely related simian and human immunodeficiency viruses (SIV and HIV) are locked in an arms race, exerting strong selection on each other over long-term coevolution. The primate innate immune systems use APOBEC3G to hypermutate the viruses, and the viruses fight this with a specific virion infectivity factor (Vif) which targets APOBEC3G for destruction. However, a previously common method of looking for evidence of coevolution, matching host and virus phylogenies, which was once thought to be strong evidence of long-term relationships between RNA viruses and their hosts, has faltered with increased investigation. Fast evolving RNA viruses tend to host-jump, and often to phylogenetically related hosts, so RNA virus phylogenies can match host phylogenies for other reasons, and with increased sampling many RNA virus trees no longer match those of their hosts. Overall, the majority of measurable viral adaptation is to hosts that are not appreciably coevolving, given the timescale of observation. Most viral evolutionary biology focuses on the evolution of the virus, and considers the host more static. An important exception to this is adaptive immune systems that can and do change on timescales relevant to observable viral evolution.

Viruses are Under Selection by Factors Other Than Host Cells

In addition to the essential interactions with their hosts, viruses interact with each other at the population level (intraspecific) or with other viral species (interspecific). For instance, strong intraspecific competition for host cells among the bacteriophage $\phi 6$ drove the evolution of a phenotype that evolved to infect novel bacterial strains (host range expansion). This new phenotype could escape the intense competition by infecting the novel strains, and was favored even though the novel host was a less productive host and the expanded host range mutant virus had fewer offspring in that host. Viruses have evolved mechanisms to outcompete each other within the same cell as well. For instance, superinfection exclusion occurs when a preexisting infection prevents the host from being infected by the same or a closely related virus. This has been broadly observed across host taxa, *e.g.*, Hepatitis C virus (HCV) infection can prevent infection with another strain of HCV. Cooperative interactions can also occur during infection. Coinfection by potato virus Y (PVY) and potato virus X (PVX), which despite their similar names come from different viral families, is synergistic, both exacerbating disease symptoms and dramatically increasing the titer of PVX when compared to single infections. These 'social' interactions among viruses can also influence viral evolution.

The environment beyond the host cell can also select for different viral phenotypes. During transmission between hosts, there can be strong, even lethal, selection pressures from desiccation, pH changes, UV radiation, and high temperatures. In human environments, sanitation of surfaces also exerts a selective pressure on RNA viruses. Experimental evolution studies have shown that viruses can evolve in response to selection on survival. For instance, VSV can evolve increased thermostability outside of the cell and human echovirus 11 can become more tolerant to UV light by lowering its mutation rate.

Genetic Drift

While it is tempting to assume that beneficial mutations will always increase and deleterious mutations will always disappear from populations, this assumption is flawed. Allele frequencies can fluctuate due to sampling effects in bottlenecks by the process of genetic drift, rather than as a consequence of selection on fitness. From a mathematical perspective, the current generation is essentially a sample of the previous generation (plus mutation). In the absence of selection, the frequency of alleles present in the current generation would be solely based on their frequency in the previous generation. The presence of selection increases the frequency of alleles associated with higher fitness and reduces the frequency of alleles associated with lower fitness. However, random chance leads to sampling error, producing deviations between the expected and the observed allele frequencies. The smaller the population, such as in a population bottleneck, the greater these deviations are likely to be. Through this sampling error, genetic drift can cause beneficial alleles to decrease in frequency and even bring deleterious alleles to high frequency.

With their high mutation rates and often large population sizes, one might expect RNA viruses to escape the effects of genetic drift. However, RNA viral populations are only intermittently large, and it is during those times when population size is restricted that genetic drift can be detected. RNA viral populations experience bottlenecks at multiple steps during infection, for instance, during transmission between hosts, between tissues in a multicellular host, and in vectors. These small population sizes allow sampling error to overwhelm the effects of natural selection, which can have lasting effects for the virus population post-bottleneck. This effect is well-studied in vector-borne viruses. The bottleneck from aphids to new plant hosts has been quantified in potato virus Y and the multipartite cucumber mosaic virus, and both showed only 1 or 2 complete viral genomes pass on to a new host. The longer-term effects of drift have been studied in cucumber mosaic virus, where plant-to-plant transmission significantly reduced genetic variation. In mammalian RNA viruses like Venezuelan equine encephalitis virus and dengue, the transmission from mammal to vector is associated with tight population bottlenecks, and drift (not selection by vector cells) primarily explains the pattern of genotypes that move into the vector.

As a note on nomenclature, genetic drift has nothing to do with "antigenic drift," a term most commonly used in Influenza evolution, which is the result of natural selection to avoid immune recognition. Genetic drift is the explanation for the random change in allele frequencies – the complement to natural selection, which is responsible for non-random changes in allele frequencies.

The Quasispecies Concept

Since RNA viruses have such high mutation rates, a population of RNA viruses descended from a single ancestor is more diverse than one founded by, say, a dsDNA herpesvirus. A parent RNA virus may produce offspring where none, or only a few, are genetically identical to the parent. This has prompted some to argue that RNA virus populations (and other genomic parasites with certain high mutation rates, such as viroids, or single-stranded DNA viruses) should be considered the unit of selection instead of an individual genotype. That is, a central, or master, sequence and all of its near mutational neighbors (one or a few mutations away from the master sequence) would be the “individual” that natural selection could affect. This shift in the unit of selection allows for the cooperation of multiple genotypes as part of the same “individual” population. There is developed mathematical theory to model and describe the behavior of RNA virus quasispecies populations. However, there is significant controversy about whether or not RNA viruses have high enough mutation rates to achieve quasispecies dynamics without additional mutagens and strong mathematical arguments showing that the same population genetics (a branch of evolutionary biology) equations that describe cellular life explain the dynamics of RNA virus populations. Therefore, there is not a necessity to invoke a different frame for evolution for RNA viruses, and doing so might not even be applicable. Perhaps as a means of satisfying these two camps within evolutionary virology, the word “quasispecies” will be frequently invoked as describing the mutant cloud of descendant sequences expected during the growth of an RNA virus population – as a synonym for genetic diversity. While some RNA virologists use the conclusions from quasispecies theory to drive their RNA virus research forward, much of the community remains to be convinced by one or more experiments that demonstrate quasispecies dynamics that cannot be otherwise explained with current, widely accepted evolutionary biology theory.

Additional Constraints on RNA Virus Evolution

Genomic architecture can affect the evolution of all biological entities, but it has noticeable and significant effects on viruses. Single-stranded RNA viral genomes form stem-loop structures, where some of the genome becomes double-stranded. This alters the evolvability of the stem regions, which evolve more slowly than loops. Regions that frequently form stems are therefore more conserved, and if a rare positively selected mutation occurs in a stem, typically its complementing base also has to change – with likely neutral or deleterious effects – for the beneficial mutation to rise in frequency in the population. This constraint on stem evolvability has been demonstrated in HIV, one of a handful of RNA and retroviruses that have had their secondary structures fully experimentally mapped, and not just inferred from sequence.

RNA viruses, like DNA viruses and cellular life, can also have overlapping reading frames: where the same stretch of RNA have multiple coding regions, offset by one or two nucleotides so that different codons are read by the ribosome. Overlapping reading frames are thought to help RNA viruses maximize the utility of their limited genome sizes, though most overlapping regions are not substantial in length (<100 bases) and involve the overlap of the ends of two genes. The less common overlaps where one gene is overprinted into another reading frame for the bulk of a gene poses a strong constraint on the evolution of the region that does double duty – encoding two proteins that are likely both essential for virus function. In eukaryotic RNA viruses that express limited numbers of cistrons, some of these overlapping reading frames are caused by ribosomal frameshifts. This can lead virologists to discovering a novel ORF in otherwise frequently sequenced and studied viruses. Two examples would be the fourth open reading frame, *vf1*, discovered in murine norovirus, and the pretty interesting potyvirus open reading frame (*pipo*) which is entirely nested within one of the genes in potyviruses’ genomic polyprotein. In the latter case, *pipo* was discovered because of its constraining effect on potyvirus evolution – there was a noticeably lower d_N/d_S ratio in the same place in multiple potyvirus species, and researchers sought an explanation for the stronger purifying selection.

Conclusions

Like all areas of science our understanding of the mechanisms of RNA virus evolution is tempered by knowing that virologists and evolutionary biologists do not yet know everything. The RNA viral biosphere is undersampled relative to cellular life, and relative to DNA viruses. There may well be RNA viruses lurking in understudied hosts or environments that will expand the ranges of RNA virus mutation rates, genome length or recombination proclivity. Novel host defense mechanisms that alter viral genomes may be discovered, contributing to additional mutation biases. However the details change, the mechanisms that underlie all biological evolution will still hold in RNA viruses: variation that arises in a population through mutation, recombination or migration rises or falls in frequency due to selection and drift.

Glossary

Adaptation vs. Evolution Here we use the term “adaptation” to refer to events that occur within a host, and “evolution” to refer to those that occur over much longer spans of time. This allows us to highlight that local adaptation within a host is due to different selective pressures than those that impact transmission to new hosts, or that act across multiple generations of hosts.

Consensus genome This term refers to a genome derived by selecting the most commonly observed allele detected at each genomic position in a sequencing-based analysis of a virus sample. Compare this term to “minor variant” below.

Fossilized or endogenized viral genome When viral DNA becomes integrated into the host's germline, these endogenous viruses can be vertically transmitted. These endogenized viruses represent a molecular fossil record of past viral invasions.

Horizontal gene transfer (HGT) Refers to the movement of a fragment of genetic material between unrelated species. Viral HGT can occur between host and virus, between two viruses, or between a virus and a coincident species that enters the same host cell. Viruses are thought to be major mediators or vectors of HGT, due to their ability to introduce genetic material into new host cells and to infect multiple closely-related host species.

In vivo vs. in vitro These terms are used here to distinguish between experiments conducted within a complex host organism (*in vivo*), vs. within cells in culture (*in vitro*).

Latency A phase where a herpesvirus is present as an episome in a host cell nucleus, mostly quiescent, and not producing any lytic viral progeny.

Lysogeny A phase where bacteriophage or archaeal viruses integrate into their host genome and are propagated along with the host genome as the cell divides.

Minor variant A sequence variant which is not the most common allele in a given virus population (e.g., within an infected host). Compare this term to “consensus genome” above.

Persistent or chronic infection This term is used to refer to a long-lasting viral infection, i.e., one that exceeds the time frame of an acute infection for that virus species.

Recombination (homologous vs. non-homologous) This term refers to the joining of DNA segments after a break. Homologous recombination encompasses several mechanisms such as strand invasion, single-strand annealing, and microhomology-mediated end-joining. Non-homologous recombination involves end-joining without any homology required.

Single nucleotide polymorphism (SNP) This term is used here to denote a single nucleotide difference (allele), which is observed when comparing sequenced isolates of a given viral species.

Standing variation This refers to a viral population that contains more than one allele or variant at a given locus, or at multiple loci in the genome (e.g., within a single infected host or within a group of hosts). See also the term “minor variant” above.

Tandem repeats Short repetitive elements found in any nucleotide sequences. These are categorized based on the length of their repeating unit, n , as follows: homopolymers ($n = 1$ base pair, bp), microsatellites ($n < 10$ bp), macrosatellites ($n \geq 10$ bp), minisatellites ($n \geq 100$ bp).

Transposable elements (TEs) Transposons are segments of DNA that can move, as a unit, from one location in the genome to another.

Introduction

A historical view of viral evolution might suggest that the evolutionary processes of RNA and DNA viruses adhere to distinct and non-overlapping rules. RNA virus evolution, as covered elsewhere in this volume, involves error-prone polymerases, an inability to perform error-correction (except in rare cases such as the coronaviruses), the existence of viral quasispecies, and a constant interplay of mutation and fitness-based selection. In contrast, DNA virus evolution is often discussed in more sweeping historical terms, with a focus on how evolution has led to speciation through the slow accumulation of genetic drift and relatively rare fixation of recombination-based genetic shifts. However, there is actually much in common between the mechanisms of evolution for both RNA and DNA viruses. For instance, while the polymerases used by DNA viruses are less error-prone and can perform error-correction, the larger size of many DNA virus genomes still leaves room for the accumulation of genetic variation in every round of viral replication. Furthermore, evidence from multiple DNA viruses suggests that rather than being rare, recombination between DNA virus genomes is rampant. The progeny of these genetic exchanges go unnoticed when recombination occurs between identical or highly similar genomes, or if the progeny do not survive fitness-based selection. Host-linked evolution or co-divergence may also contribute to the apparent low mutation rates in DNA viruses. Understanding the factors that determine the rate at which viral genomes generate and fix mutations provides essential insights into their evolutionary mechanisms. We

Fig. 1 DNA virus evolution relies on molecular mechanisms (top, shaded gray) which are impacted by host biology (arrayed below). DNA viruses exist in a range of genome formats (center) and sizes, each of which has a different propensity to evolve via these mechanisms. Viral genome formats include circular and linear DNA that is either single- or double-stranded, with lengths ranging from ~ 2 to > 2000 kbp. The molecular mechanisms that underlie DNA virus evolution include single nucleotide changes, recombination and horizontal gene transfer, fluctuations in tandem repeat length, and sequence gain or loss through insertions, deletions, and segment duplications. Host impacts on DNA virus evolution (listed clockwise) include host cell architecture (e.g., nucleated vs. non-nucleated host cells), the time frame being considered (e.g., one round of infection or many generations), the host complexity (single-cells vs. complex organisms), an acute vs. long-term persistent duration of host infection, selective pressures and bottlenecks that act on each virus population, and co-divergence with host species over millennia. Image created using BioRender.com and Adobe Illustrator.

cover these topics in greater detail below, after introducing a number of additional considerations to the discussion of how DNA viruses evolve (see Fig. 1 for summary).

Diversity of DNA Virus Genome Types

A simplistic division of evolutionary mechanisms for viruses is generally split based on whether the genome being considered is RNA or DNA. While a single-stranded RNA virus and a double-stranded DNA virus might be considered typical exemplars of each group, these are by no means the only genome types — there are numerous variations on these themes. The prototypic double-stranded DNA (dsDNA) viruses exist in both linear and circular forms. These dsDNA viruses run the gamut in terms of size, from tiny (~ 5 – 8 kilobase pairs, kbp) papillomaviruses and polyomaviruses, to large bacteriophage, adenovirus, and herpesvirus genomes (ranging from ~ 30 – 250 kbp), to the over-sized nucleocytoplasmic large DNA viruses (NCLDV) such as poxviruses and phycodnaviruses (~ 130 – 400 kbp), and finally the giant viruses found in algae and amoeba (upwards of ~ 1 – 2 megabase pairs, Mbp). There are also unusual genome formats among these dsDNA viruses, for instance, the covalently-closed ends of linear poxvirus genomes, or the partially gapped circular dsDNA genome of hepadnaviruses (e.g., hepatitis B virus). Also, there are abundant examples of single-stranded DNA (ssDNA) viruses, which include both linear (e.g., parvovirus and densovirus) and more numerous circular forms (e.g., circovirus, nanovirus, and geminivirus; these are also known as Circular Rep-Encoding Single-Stranded or CRESS DNA viruses). In each case, these genome formats lead to particular constraints and opportunities for the evolutionary mechanisms discussed here. We describe the evolutionary mechanisms below in light of the most common dsDNA virus examples, and where possible, we note those areas where other DNA virus genome formats may differ.

Host Cell Biology and Availability of Host Enzymes Constrains Virus Evolution

It is possible – though not advisable – to discuss the mechanisms of DNA virus evolution without considering host cell biology. This simplification is enabled by the fact that all known hosts for these viruses are DNA-based life forms, with the concomitant presence of the requisite machinery of a DNA polymerase for replication, RNA polymerase for transcription, and ribosomes for translation. The most apparent distinctions among potential hosts for DNA viruses fall along the known bifurcations of the tree of life – namely bacteria, archaea, and the major groups of eukaryotes (i.e., plants, animals, fungi, and protists). In bacterial and archaeal hosts, the absence of a nucleus removes any distinction in where DNA virus replication occurs. However, in eukaryotes, many host enzymes are constrained to the nucleus, including host DNA and RNA polymerases as well as the RNA splicing machinery, whereas translation is limited to the cytoplasm. Viruses that utilize the host DNA polymerase to copy their genomes, such as members of the *Polyomaviridae* and *Papillomaviridae*, must therefore replicate in the nucleus. Likewise, while the *Herpesviridae* and *Adenoviridae* encode their own DNA polymerase, they use the host RNA polymerase and splicing functions, restricting their replication to the nucleus. In contrast, members of the *Poxviridae* and *Mimiviridae* that replicate in the cytoplasm

encode their own DNA and RNA polymerases, whose fidelity can, therefore, evolve on a separate trajectory from that of the host. Finally, while ssDNA viruses use host DNA polymerases, their observed mutation rate far exceeds that detected in their host-cell genomes or in dsDNA viruses, suggesting that other sources of mutation such as oxidative damage and/or lack of DNA repair may be at play. For these reasons, knowledge of the host cell biology and the usage of host enzymes by a given virus species is a requirement for understanding the constraints on viral evolution.

Time Frames: Viral Adaptation Within a Host vs. Evolution Over Multiple Generations

Any discussion of the mechanisms of virus evolution needs to begin by defining the time scale under consideration. At the shortest end of this spectrum lies the time frame of a single round of viral infection. As noted below, the first infected cell may be anything from a single-celled organism to the first cellular entry point into a complex human host. From a clinical perspective, viral infection and disease are often considered on the time frame of a single individual's infection – often a human or animal subject. As described below, the virus population within a given host may undergo adaptation within the relatively short time frame of the host's infection. Mechanisms that enable diversification or speciation of a given virus usually require thousands of viral replication cycles, encompassing multiple host generations. At the grandest scale, the origins of viruses and specific lineages thereof spans the history of life on earth. The origins of viruses as we know them are covered elsewhere in this volume, so here we focus solely on the mechanisms that form the foundation of all viral adaptation and evolution. As such, we focus mostly on the time scale of an individual cell and/or host infection, which can include the contributions of virus populations that are more diverse and/or less fit than those which we see preserved over longer sweeps of evolutionary time.

DNA Virus Hosts Vary From Single Cells to Complex Multi-Cellular Organisms

An understanding of DNA virus adaptation and evolution requires a consideration of the host as a single-cell versus a complex multi-cellular organism. A basic theoretical model of viral replication would include productive viral replication in a single cell, followed by spread to nearby uninfected cells, potentially over multiple generations. This model may well apply to bacterial and archaeal cells, and to single-celled eukaryotic species such as marine alga or amoeba. However in most cases, more complex eukaryotic organisms, from plants to animals and humans, require a complicated series of steps for successful virus propagation and spread. These steps include entry via an accessible portal of the organism, dissemination within the organism to reach susceptible cells, evasion of host defensive responses (including innate and adaptive immunity), and egress to allow for potential spread to new hosts. There is ample evidence that evolution acts within a single host, although for the sake of clarity we will refer to these intra-host events as “adaptation” rather than evolution. Using these terms allows us to highlight the distinction that local adaptation within a host is due to selective pressures that differ from those that impact transmission to new hosts, or that act across multiple generations of hosts. Also, the virus population within a complex organism may partition into distinct environmental niches within the host. For instance, the genomic diversity of human cytomegalovirus (HCMV) in patient samples is often analyzed from blood samples, and yet this viral population does not directly represent a common source of natural virus transmission between hosts (e.g., saliva). Studies of virus evolution need to carefully consider the source material used in examinations of viral diversity, and how this choice may influence the resulting observations of evolutionary fitness.

The Contributions of DNA Virus Persistence and Chronic Infections

We referred above to a theoretical model of DNA virus replication that involved productive replication in a single cell and spread into nearby uninfected cells, across multiple viral generations. An underlying assumption in such a model is that multiple rounds of productive infection occur sequentially. However, the lifecycle of many if not most DNA viruses exhibit other phases of existence, namely through persistence and chronic infections. For many bacteriophage and archaeal viruses, a common strategy is the well-known cycle of lysis versus lysogeny. For these viruses, the productive and often cell-destructive strategy of lytic replication is interleaved with phases of lysogeny, when the viral genome integrates into the host genome and is propagated as part of the host genome during cell division. A similar strategy exists for the large family of herpesviruses that infect most animal species and humans, with the long-term non-lytic phase being termed latency instead of lysogeny. An important distinction is that with a few notable exceptions, integration into the host genome is not a normal part of herpesvirus latency. Instead, these herpesviruses remain episomal in the host nucleus during lifelong latency. At the molecular level latency can be defined by the absence of significant viral replication and limited viral gene expression. Herpesvirus episomes can undergo sporadic reactivation to produce new viral progeny, which is followed by additional cycles of latency and reactivation. Similar to herpesviruses, certain members of the *Adenoviridae* can progress from a lytic infection of epithelial cells to a latent infection in T-lymphocytes of the tonsils and other adenoid tissues. The ability to establish a long-term infection is thus a vital part of the viral lifecycle of many DNA viruses, which contrasts with the acute infectious period of many RNA viruses (e.g., influenza virus or rotavirus). Persistence and chronic infections motivate the need to explore the contributions of within-host variation and adaptation to the evolutionary mechanisms of DNA viruses.

In addition to latency and lysogeny, virus persistence or chronic infection includes a whole class of DNA virus infections where viral replication is readily detected in the host, but the infection is not cleared for a significant length of time. Many smaller DNA

viruses such as papillomaviruses, polyomaviruses, and certain members of the *Circoviridae* use this “low-and-slow” approach. These viruses replicate in actively dividing cells, but have evolved to avoid detection by the host immune system. Interestingly, many of these viruses appear to be pathogenic only if the virus persists for an extraordinarily long time. For example, in most cases, the host immune system will eventually clear human papillomavirus infections. This process typically spans several months if not years. However, a long-term infection (> 2 years) dramatically increases the risk of virus-induced cancer. Similarly, while polyomavirus infections in humans are typically asymptomatic, long-term persistence of JC polyomavirus causes complications in immunocompromised hosts. In these hosts, the otherwise benign infection can spread into the nervous system, where the viral infection can then induce significant damage (as discussed further below). The duration of animal lifespans, as opposed to single-celled hosts, means that long-term persistent viruses of animal cells have evolved to have significantly more interactions with their host’s immune system during lifelong latency, than are observed during bacteriophage or archaeal virus lysogeny. Recent advances in high-throughput sequencing technology are now enabling researchers to interrogate whether mutations in viral genomes are specifically correlated with disease progression in these chronic infection settings.

Co-Divergence With Hosts as a Driver of DNA Diversification

A common perception is that RNA viruses mutate rapidly while DNA viruses are slow and stable. This may stem from the view that the diversity of many DNA viruses can be explained by co-divergence with host species, thus placing viral evolution on a timescale of millions of years. Long-term co-divergence and consequently low rates of nucleotide substitution have been supported in some DNA viruses; however, this is likely only part of the equation. The development of new sequencing technologies and the ability to include temporal information into molecular clock models allows us to estimate the rate and timescale of virus evolution independent of the (strong) assumption of co-divergence. Indeed, many DNA viruses show evolutionary rates close to those of RNA viruses, which themselves span a range of mutation rates. It is important to note that time-structured sequence data spanning years or decades often contain short-lived polymorphisms. Researchers should thus use caution when comparing mutation rates at such distinct evolutionary scales.

Nonetheless, for many viruses, it is essential to acknowledge that both short and long timescales may provide valuable information. While there is strong evidence supporting co-divergence of the *Polyomaviridae* with their hosts, recent studies have demonstrated the need to account for faster evolution within this virus family. In immunocompromised patients, mutations in the JC polyomavirus capsid protein allow it to escape neutralizing antibodies and invade the central nervous system, causing an opportunistic brain disease called progressive multifocal leukoencephalopathy (PML). The ability to evade the immune system – while remaining extraordinarily stable over longer timeframes – suggests that the *Polyomaviridae* evolve at two distinct rates. In the case of ssDNA parvoviruses, researchers seeking to understand the determinants of host range variation have tested the outcome of culturing several closely related viruses ($>98\%$ nucleotide identity) in cells derived from phylogenetically distinct hosts. The authors found that canine parvovirus (CPV-2) underwent extensive mutation during passage in non-native host cells, while no mutations arose in cells from the native host. These data indicate that the virus was well-adapted to its current host species, but that multiple mutations in its surface protein were needed for it to infect diverse host species efficiently. These data illustrate how long-term host dependency may constrain evolutionary rates in many DNA viruses.

Single Nucleotide Differences as a Measure of Evolutionary Change

Specific mutations such as single nucleotide polymorphisms (SNPs), insertions, and deletions (together termed in/dels) are likely to experience different selection dynamics, which impact the chances that these variations become fixed in the population. However, unlike for nucleotide substitutions (i.e., SNPs), the methods for measuring the evolutionary rate of insertions and deletions (in/dels) are not well developed. Because of this limitation, our understanding of viral evolution is primarily based on measuring the accumulation of SNPs over time, which ignores the potentially critical influence of other sources of variation, such as in/dels, tandem repeat fluctuations, and recombination (discussed further below). Recent studies have also provided evidence that viral evolutionary rate estimates decrease as their measurement timescales increase. This is evident in the field of paleovirology. For example, “fossilized” hepadnavirus DNA integrated into bird genomes suggests that these viruses are at least 19 million years old. In turn, this implies a significantly slower evolutionary rate than what was predicted based solely on extant viruses.

Early studies on the mutation rate of DNA viruses using single-gene or single-locus analyses estimated a mutation rate on the order of 1×10^{-7} to 1×10^{-8} substitutions/site/year. These values have been further supported by genome-wide comparisons for a handful of large DNA viruses. For instance, a recent study used a high-fidelity high-throughput sequencing (HTSeq) technique called duplex sequencing to detect spontaneous mutations in clonal lineages of human adenovirus 5, and the authors found that these occurred at a rate of 1.3×10^{-7} per base, per infection cycle. This rate matches well to a genome-wide estimate of the *in vitro* and *in vivo* mutation rates for murine CMV, which was obtained by shotgun Sanger approaches just before the development of HTSeq ($\sim 1 \times 10^{-7}$ mutations per bp per day). These low mutation rates are often cited by those wishing to contrast DNA virus stability with RNA virus diversity. However, data from both modeling and newer HTSeq-based comparative genomics studies have indicated that large DNA viruses may have mutation rates closer to 1×10^{-5} or 1×10^{-6} . In our comparisons of sub-clones generated from a parental population of herpes simplex virus 1 (HSV-1), we observed 3%–4% variation between sub-clones,

genome-wide. Other studies of HSV have shown that antiviral drug resistance mutations can be selected from a naïve virus population in just one round of viral passage *in vitro*. These data suggest that at least under certain circumstances, standing variation is maintained in DNA virus populations. An alternative or additional theory is that *de novo* mutations may occur at specific genomic regions more often than others (e.g., hot spots). The wider application of genome-wide measurements of viral variation will help to elucidate these possibilities.

***In Vivo* Observations of Within-Host Diversity and Adaptation of DNA Viruses**

Recent advances in high-throughput sequencing have now enabled the detection of minor variants within a single viral isolate or patient. These minor alleles can manifest as a new dominant allele or genotype after population bottlenecks or selective pressures such as antiviral therapy. Evidence of sequential takeover by distinct HCMV strains has been observed in immunocompromised adult patients, demonstrating both the existence of co-infections as well as the opportunities for recombination and/or subsequent selection. Studies of vaccine-associated rashes for varicella-zoster virus (VZV), and of congenital infections by HCMV, have demonstrated the potential for niche-specific adaptation or segregation of viral variants within specific body sites of infected hosts. For human papillomavirus 16 (HPV16), a recent study of several thousand women used a combination of PCR and Illumina-based HTSeq to reveal an unexpectedly high level of viral genetic variability. Of note, there was higher HPV16 genetic variability between patients than within a single patient, suggesting that many of the identified sequence differences were specific to each patient. Interestingly, women with pre-cancerous lesions had significantly less variation than women with a productive (early stage) HPV16 infection, confirming that cellular transformation by HPV represents a genetic bottleneck. This high level of inter-patient variability demonstrates that, at least within some settings, the mutation rate for HPV must be significantly higher than the previously estimated 2×10^{-8} nucleotide substitutions/site/year for the viral coding genome. Importantly, the higher-than-expected rate of inter-host evolution argues against the notion that a subset of (oncogenic) human papillomaviruses were acquired by archaic hominins during their migration out of Africa. Together these data indicate that many DNA virus populations may contain and/or generate standing variation following infection. It also appears that this variation is not often transmitted to a new host. The lack of successful transmission of these minor variants suggests that the standing variation in viral populations only becomes phenotypically apparent after population bottlenecks or selection. Importantly, these studies provide corroborating evidence that the molecular mechanisms of DNA virus evolution which have been demonstrated *in vitro*, also operate *in vivo*.

Fluctuations in Tandem Repeat Copy Number as a Mechanism of Evolution

Changes in the length or copy number of tandem repeats (TRs) provide another mechanism of virus evolution. Short TRs are usually categorized into three groups: homopolymers, which are sequential repeats of a single base (e.g., 5 or more C's in a row); microsatellites, which have a repeating unit of <10 base pairs (bp); and mini- or macrosatellites, which include repeating units of 10–500 bp. The mechanisms of repeat expansion or contraction vary by the repeat size. Homopolymer-based length variants are presumed to arise primarily through polymerase slippage, whereas larger TRs may arise either by template looping during polymerase progression or through recombination as discussed below. The repeating units of TRs may be perfect copies or include minor imperfections in the repeating sequence, and these repeats can occur in both coding and non-coding regions. In coding sequences, repeated elements may contribute to structural units of protein folding (e.g., turns of an alpha-helix) or provide variable lengths of unstructured regions within a multi-domain protein. Noncoding repeats have been shown to include promoter elements, chromatin or insulator binding motifs, as well as secondary structural elements such as quadruplexes and other motifs.

For many tandem repeats, the only viral data available is their conservation of position in the genome of a given species, and perhaps data on the degree to which a given TR varies in length across different virus isolates of the species. Functional roles have been demonstrated for select TRs in just a handful of DNA viruses. In the few herpesvirus species that have been shown to integrate into a host genome, there are viral telomeric repeats that function in their integration into the host. In other non-integrating herpesviruses, length variations at homopolymeric tracts in the thymidine kinase (TK) and polymerase genes are a common route of viral escape from the antiviral drug acyclovir. Ribosomal frameshifting of defective transcripts in these drug-resistant genomes allows the translation of a low level of functional TK or polymerase, enabling viral survival even in the face of an otherwise disabling mutation. Fluctuations in TR lengths have also been described for JC polyomavirus populations in patients. In this case a predominant polyomavirus genotype, or archetype, is shed in the urine of most infected individuals, while rearranged forms with deletions and TR variations are found in the brains of patients with PML disease. For poxviruses and other large DNA viruses, restriction fragment length polymorphisms (RFLPs) have often been used to track changes in the dominant virus genotypes and TRs over time. In a recent study of myxoma virus (a *Poxviridae* member), the predominant RFLP type was observed to change each year. Expansion of the inverted terminal repeat boundaries appears to provide myxoma virus with an opportunity for evolution. Likewise, the genome of the vaccinia poxvirus shows similar heterogeneity of the terminal repeats. Repeated plaque based purifications have shown that heterogeneity in the terminal repeats can evolve rapidly from the DNA of a single vaccinia virion. As technologies to track fluctuations in the length of TRs improve, it will no doubt become easier to examine these changes and gain a better understanding of their contribution to virus adaptation and evolution.

Large DNA Viruses Undergo Frequent Recombination

Recombination can serve as a driving force for evolutionary shifts in DNA viruses, akin to the genetic shifts that result from reassortment in segmented RNA viruses. Recombination can be classified as homologous recombination – between like sequences – or as illegitimate or non-homologous recombination. For most large DNA viruses, the potential of the viral genome to recombine has been studied by analyzing phylogenetic relationships between naturally circulating viral genomes. Among the adenoviruses, which include seven species (human adenovirus A-G) and multiple serotypes, recent studies applying HTSeq-based comparative genomics have demonstrated both intra-species and interspecies recombinants – often in association with pathogenic infections. For instance, a naturally circulating intratypic recombinant of human adenovirus subtype C was found to be the etiologic agent of severe acute respiratory infections in children in China. There are also examples of both historical and recent isolates of pathogenic adenoviruses that appear to have arisen from zoonotic transmission and recombination between simian and human adenoviruses. For the beta-herpesvirus HCMV, multiple studies have demonstrated a history of rampant recombination between the genomes of different isolates. Particular sections or islands of the HCMV genome appear to have co-segregated, while widespread recombination between strains has created a mixture of alleles elsewhere in the genome. It is thought that genes in these islands are co-dependent, thus placing a fitness cost on any recombination events that occur inside these regions. Similar levels of within-species recombination have been shown for most herpesviruses with sufficient genome sequence availability to make these comparisons. Recently, data supporting potential inter-species recombination among these viruses have been observed as well, with HSV-1-like DNA detected in several loci of the HSV-2 genome. Likewise, a virulent avian herpesvirus that created an outbreak in Australian poultry was revealed to be a spontaneous recombinant derived from two live-attenuated vaccines in use in the area. For large DNA viruses such as herpesviruses and poxviruses, laboratory co-infection studies and analysis of recombinant progeny by HTSeq have further defined the genome-wide potential for recombination and begun to define hot spots or regions with a higher propensity to recombine. Together these data demonstrate the extensive role of recombination in the evolution of both nuclear- and cytoplasmic-replicating large DNA virus genomes.

Recombination at Different Frequencies for Small DNA Virus Genomes

Large DNA viruses appear to recombine more readily than the small dsDNA viruses of the *Papillomaviridae* and *Polyomaviridae*. Even under controlled experimental conditions, no conclusive evidence for recombination within these two virus families has been described. One theory for this lack of observable recombination is that smaller viruses have fully optimized the usage of their genomic real-estate, such that recombination events would be highly likely to interrupt co-dependent genes or regulatory sequences – and thus carry too high a fitness cost to survive. However, phylogenetic analyses have identified evidence for several recombination events within the *Papillomaviridae*. As in HCMV, it appears that ancient recombination has segregated functional regions of the viral genome, separating the genes coding for non-structural proteins from the structural genes. Recombination does not appear to play a significant role in the short-term adaptation of the papillomaviruses, implying that recombined daughter viruses are not as fit as the parental genomes. Supporting this hypothesis, even when evidence of HPV16 recombination was detected within a single patient, these recombinant genomes were incapable of sustained replication within the host. Similarly, while phylogenetic analysis can detect evidence for ancient recombination near the root of the *Polyomaviridae* phylogenetic tree, recombination does not appear to be a significant component of ongoing polyomavirus evolution. However rare recombination events can and do contribute to virus evolution. For instance, conservation efforts to prevent the extinction of the western barred bandicoot have been hampered by an outbreak of the bandicoot papillomatosis carcinomatosis virus type 1 (BPCV1), a recombinant between an ancestral papillomavirus and polyomavirus. This virus is a hybrid that appears to have recombined the structural genes of the *Papillomaviridae* with the non-structural genes of the *Polyomaviridae*. These examples illustrate how rare and unusual recombination events can enable the dramatic expansion of viral evolutionary sequence space.

Despite being roughly the same size as the *Polyomaviridae*, single-stranded DNA viruses recombine relatively efficiently. Single-stranded parvoviruses have shown an ability to jump to new hosts rapidly, and recombination along with a relatively high mutation rate has been hypothesized to underlie this ability. Parvoviruses have also been demonstrated to readily recombine in cell culture. Although the mechanism of parvovirus recombination is not known, a role for viral secondary structure has been proposed. Indeed, the parvovirus origin of replication forms a hairpin structure that is a recombination hot spot, potentially due to stalling of DNA polymerase at this secondary structure. Template swapping before re-initialization of replication could then result in the formation of a chimeric genome. Alternatively, parvovirus replication may create intermediate concatemers. Resolving these concatemers may activate DNA repair enzymes, leading to the creation of mosaic viruses through the homologous recombination repair system. While recombination appears to play an essential role in the evolution of ssDNA viruses, these viruses appear to have adapted to minimize combinations of incompatible regulatory elements. For example, the gene encoding the replication protein (Rep) and the cis-acting elements that interact with the replication protein are usually within 100 nucleotides of one another. This ensures that the replication machinery is highly likely to remain together and compatible following any recombination events. A detailed comparison of recombination patterns within ssDNA viruses also found that breakpoints tend to fall outside of known genes. These observations imply that viruses expressing recombinant proteins are not usually tolerated.

Duplication and Deletions of Genes and Genome Segments

The outcome of recombination within identical or highly similar genomes is rarely noticed, except for occasions where this event leads to gene duplication or loss. Evidence of gene duplication and subsequent divergence is prevalent in adenovirus genomes. Ancient incidents of gene capture presumably produced those adenoviral gene products with similarity to host genes or those of other viruses, which are found across many adenoviral genera. Other more evolutionarily-recent duplications are found in smaller subsets of adenoviral species. The phenomenon of gene loss has been well-documented in herpesviruses, where across the diverse alpha-, beta-, and gamma-subfamilies of the *Herpesviridae*, many examples of gene loss have been found during viral propagation *in vitro*. The phenomena of genetic drift and gene loss were first detected in laboratory-passaged strains of the beta-herpesvirus HCMV, where the gene regions lost *in vitro* were later found to have functions associated with cell tropism and immune evasion *in vivo*. The extremely large mimivirus dsDNA genome has also been shown to undergo gene loss from both its termini during repeated passage in an amoebal host. In mimivirus, this gene loss was associated with a phenotypic change in virions, which was visible as a loss of fibrils on the virion surface.

In contrast to gene loss, the duplication of genetic segments – a gene accordion – has been best demonstrated by a series of elegant studies in poxviruses grown *in vitro*. These studies showed that expansion of gene copy number could provide functional fitness recovery after deletion of a core viral gene, by driving higher expression of a less-efficient gene version. This expansion also enabled the adaptation and eventual evolution of improved function, via mutations that occurred in the redundant copies of this gene. Whether or not this type of gene accordion occurs for DNA viruses that replicate in the nucleus remains to be determined. The segregated nature of nuclear replication and transcription, followed by translation in the cytoplasm, means that nuclear-replicating viruses will complement defects in co-replicating genomes *in trans*, since proteins made in the cytoplasm can be utilized by all progeny genomes.

Among the small DNA viruses, a subset of human papillomaviruses is associated with recurrent respiratory papillomatosis (RRP). Interestingly, these RRP-associated viruses are not typically considered as oncogenic viruses. However while RRP is considered a benign neoplasm of the larynx, involvement of the lungs is almost invariably fatal. Whole genome sequencing efforts have implicated a duplication of the viral promoter and a subset of viral genes in the RRP progression towards lung invasion. While the expansion of these loci in the papillomaviral genome is likely not important during a normal viral lifecycle, these data illustrate how duplications can provide a powerful adaptation mechanism for otherwise slow-evolving viruses.

Host-Virus Exchange via Horizontal Gene Transfer and Transposable Elements

Horizontal gene transfer (HGT) provides another avenue for evolutionary adaptation of both viruses and their hosts. HGT has been well-documented between bacterial and archaeal host species, often vectored by large DNA bacteriophages or archaeal viruses. Recent data have demonstrated that HGT may also take place between eukaryotic hosts and their viruses. For example, transposable elements (TEs) found in the moth genome have also been detected in the genomes of baculoviruses that infect these moths. Since this baculovirus infects several species of sympatric, co-occurring moths, it may well be the historical vector that moved TEs among these different host species. Other host-derived sequences were also detected in about 5% of progeny baculovirus genomes, although the co-opted host DNA was not carried beyond a few cycles of viral replication. Most of the integrated host sequences were TEs, but others appeared to result from recombination at sites of microhomology between the host and viral genomes. Most large DNA viruses are not known to integrate into the host genome as part of their overall replication strategy. Select herpesviruses of the alpha- and gamma- subfamilies do integrate into the host genome, although for these viruses it appears to be a reversible process that can lead to later excision and non-integrative replication. Marek's disease virus, an alpha-herpesvirus of poultry, and human herpesvirus (HHV) 6A and 6B, two gamma-herpesviruses of humans, integrate into host telomeres as a central part of their lifecycle. The germline or chromosomal integration of human herpesviruses (ciHHV), usually HHV6A, is detected in about 1% of the human population, although the clinical consequences of ciHHV are as yet unknown. These examples recommend the use of genome-wide HTSeq of viral populations as a means to detect horizontal gene transfer in action.

For the small DNA polyoma- and papillomaviruses, integration of all or a fragment of the viral genome into the host cell DNA is an evolutionary dead end, with an outcome that is nonetheless well-known for having the potential to induce dramatic outcomes of dysregulated cell division and tumor formation. In a recent study of HTSeq data from HPV-positive head and neck cancers, evidence was found to suggest that the HPV genome can replicate as an independent viral-human hybrid mini-chromosome, at least in some instances. These data implied that following an integration event, the viral genome may be excised from the human chromosome, creating a viral-human hybrid circular episome. Under particular circumstances, these hybrid genomes could theoretically get packaged into infectious virions. However, considering the tight regulation of papillomavirus replication, it appears unlikely that these hybrid genomes would be able to establish an infection in the next host.

Conclusions

Much remains to be resolved about the dichotomy between the measurably low rate of polymerase error in most DNA viruses, and their ability to undergo rapid genetic change in the face of intense selective pressures. However as discussed here, the multiple mechanisms of DNA virus evolution beyond single nucleotide substitutions likely provide the resources to confer this level of

evolutionary adaptability. Researchers have long agreed that ancient events of recombination and horizontal gene transfer, as well as gene duplications and subsequent divergence, could explain many aspects of virus origins. The breadth of new insights offered by high-throughput and deep viral sequencing, as well as by virus discovery and metagenomic approaches, have begun to broaden and clarify this picture. Deep sequencing has revealed the level and ubiquity of standing variation in virus populations, which provides fodder for future adaptation and selection. Metagenomic approaches and viral discovery have allowed researchers to detect novel viruses and recombinants that would have been missed using prior methods, which tracked viral presence using single-point genetic markers. These data provide ample assurance that the textbook explanation of mechanisms of virus evolution will need continued revision in the years to come, as more examples are brought forward and we expand our knowledge of how viral diversity arises and fuels virus evolution.

Introduction

Paleovirology can be defined as the study of ancient viruses and the way they have shaped the evolution of host genomes and phenotypes. Ancient viruses can be found in the form of viral genes or entire viral genomes integrated into the genome of their hosts. Some viruses, such as the retroviruses that infect vertebrate animals (family *Retroviridae*), encode all the machinery necessary to integrate their genome into that of their host. Prior to integration, the retrovirus' RNA genome is reverse-transcribed into a DNA molecule. Integration is an essential step of the replication cycle for retroviruses, which generally takes place in the somatic cells of the host. Sometimes, however, integration can occur into the genome of host germ cells. Gametes bearing such an integration may be involved in the formation of a zygote and if the integration does not impede normal development of this zygote, then all somatic and germline cells of the resulting host individual will bear the viral sequence integrated into their genome. The viral sequences, also called endogenous viral elements (EVE), can then be inherited vertically from one generation to the next and the frequency of this EVE can increase until it eventually reaches fixation in the host population, that is, it becomes present in all individuals of the population (Fig. 1). This phenomenon, often called "endogenisation", has occurred recurrently, seeding a large number of retrovirus-derived EVE in the genomes of vertebrates. For example, it has been estimated that no less than 8% of the human genome derives from retroviral EVE.

Until about ten years ago, the vast majority of EVE known in eukaryotes were retroviral sequences integrated into the genomes of vertebrate animals. Since then, many eukaryote genomes have been sequenced and it became possible to uncover a large number of new EVE originating from non-retroviral viruses integrated into the genomes of a variety of eukaryote species. Importantly, viruses are not found in the geological fossil record, such that before the discovery of EVE, it was very difficult to study viral evolution over long evolutionary periods of time. Paleovirological studies of EVE thus offer unique opportunities to trace the origin of currently circulating viral families, as well as to better understand how viruses have shaped the biology of their hosts over dozens of millions of years.

Patterns and Mechanisms Underlying Viral Integration

Endogenous viral elements are typically identified within the sequenced genome of their host using algorithms designed to detect similarities at the nucleotide or amino acid level with known viral genes. It is becoming standard to perform systematic characterization of EVE in a given set of genomes using all sequenced viral proteins as baits. There are 5,119,722 of such proteins available in the Genbank database of the NCBI as of January 2019. Searching for similarities between these proteins and eukaryote genomes usually returns a very large number of host sequences resembling viral genes, many of which are false positives that can be filtered out by implementing several filters. It is then important to ensure that the remaining candidate EVE sequences are indeed integrated into the host genome instead of deriving from circulating viruses, the genome of which could have been extracted and sequenced together with that of the host. Among other ways to verify integration, finding a DNA version of an RNA virus can be taken as a good indication of the integrated nature of this virus. Depending on the quality of the genome assembly under study, it may be useful to further verify the integrated nature of EVE by amplifying loci of interest using PCR and to resequence them using targeted sequencing.

Systematic screenings for EVE performed during the last 10 years have revealed that virtually all types of RNA and DNA viruses can integrate into the genome of their eukaryotic hosts. Endogenous viral elements have been identified in a large variety of both uni- and multi-cellular eukaryotes. These discoveries are remarkable in the sense that the majority of viruses are not able to actively integrate into the genome of their host. It is thus believed that most endogenisation events are the product of fortuitous, illegitimate recombination events between host and viral genomes that are catalyzed by host enzymes. Several analyzes of the genomic context in which EVE lie within a given genome have revealed that they are often directly flanked by transposable elements (TE). Transposable elements are sequences that have the ability to move from one locus to another in a given genome and to duplicate themselves in the process. They are found in the genomes of all organisms, often reaching high numbers of copies. The presence of such TE around EVE coupled with detailed analyzes of the molecular signatures associated with EVE integration suggest that integration of non-retroviral RNA viruses often occurs through reverse-transcription of viral RNA genomes or transcripts, which is mediated by reverse-transcriptases encoded by retroelements residing in the host genome (Fig. 1). Furthermore, some parvoviruses can integrate into the host genome by a Rep-mediated mechanism and it has been suggested that

Fig. 1 Viral endogenisation. (A) A virus (red dots) circulates horizontally within a population of cats and replicates in somatic cells. In one of the infected cats (#4), the virus is able to penetrate into germ cells and a fragment of its genome is integrated into that of the cat's gametes. The integration may have been facilitated by the reverse-transcription of the viral RNA catalyzed by the reverse-transcriptase encoded by the cat's retrotransposons. The cat bearing the viral integration reproduces with another cat devoid of integration. This crossing produces cats which bear the integrated virus in all their somatic and germline cells. If the endogenous virus does not have any deleterious effect on the cat bearing it, then its frequency can eventually increase in the cat population until it reaches fixation. (B) Top panel: structure of an endogenous retrovirus. The two black arrows correspond to the long terminal repeats (LTR) flanking each new copy of endogenous retrovirus. Gag: Group-specific antigen, processed into matrix, capsid, nucleocapsid and, in some viruses, additional core proteins. Pol: Polyprotein encoding reverse-transcriptase, RNase H and integrase functions. Env: envelope protein. Lower panel: structure of a non-retroviral endogenous viral element. This example illustrates the integration of the N gene of the genome of a mononegavirus (-ssRNA virus). The integrated N gene lies next to a host transposable element (TE), indicating that it was likely accidentally reverse-transcribed into the host genome together with this TE via template switching of the TE reverse-transcriptase.

DNA viruses in general can integrate into host chromosomes when DNA double strand breaks are repaired, through processes such as non-homologous end-joining.

Endogenous viral elements often correspond only to fragments of viral genomes. While the fragmentary nature of EVE may generally be best explained by the fact that endogenisation involved only a fragment of a viral genome, it is also possible that portions of an EVE corresponding to an entire viral genome were lost through mutations and deletions. In most cases, such degradation may affect randomly any region of an integrated viral genome. In rare instances, however, some viral genes may be recycled, or domesticated, by the host. Given the new beneficial cellular function fulfilled by such domesticated viral genes, they are less likely to be degraded than non-domesticated viral genes. The fragmentary nature of EVE may also be explained by the likelihood with which a given transcript or viral genome fragment may be reverse-transcribed, which may depend on its abundance in the host cell. Some segmented viruses such as partitiviruses, for example, typically package different amount of each genome segment in their capsid. Other non-segmented viruses such as those belonging to the *Mononegavirales* order produce six transcripts in different quantities, none of which correspond to the entire viral genome. The quantity of each transcript is determined by a 5'-to-3' gradient, with the N gene encoding the nucleocapsid located at the 5' extremity of the genome being the most transcribed. In agreement with this, the majority of EVE deriving from endogenisation of *Mononegavirales* in animal genomes correspond to the N gene (Fig. 1(B)).

Another reason which may have more to do with methodological limitations linked to the detection of EVE, might sometimes explain why we observe some viral genes more often than others under the form of EVE. For example, a study performing a systematic search of EVE in the genomes of six crustacean species revealed that the vast majority of the 210 annotated EVE corresponded to viral genes encoding non-structural proteins. It is unlikely that the observed higher abundance of non-structural proteins be explained solely by a mechanistic process because the bias was observed for all six viral groups to which the 210 crustacean EVE belong (both RNA and DNA viruses), which differ greatly in their replication cycle. Rather, the observed gene bias in endogenisation may be caused by differences in the mode and rate of evolution among viral genes. Indeed, it is known that viral genes encoding structural proteins tend to evolve faster and be less conserved than genes encoding non-structural proteins because they are more directly involved in evolutionary arms races with their host lineages. Endogenised viral genes encoding structural proteins may thus be often too distantly related to viral proteins used as baits to be detected in

similarity searches. It follows that the number of EVE that we are able to recognize in the genome of eukaryotes likely is an underestimation of the true number of EVE that have entered these genomes, and that we will be able to discover more EVE as we discover more extant viruses.

Calibrating the Long-Term Evolutionary History of Extant Viral Families

Perhaps one of the most interesting features of endogenisation is that once a virus gene enters the genome of its eukaryotic host, it basically freezes in time. In other words, it replicates only at the rate of the host genome and ceases to mutate very rapidly as it did when it was replicated by a highly error-prone viral polymerase. Given that eukaryote mutation rates are two to five orders of magnitude slower than most viral mutation rates, it becomes possible to retrieve very old EVE. Studies of the short-term evolution of viruses, including estimates of the time at which extant viruses have entered the human population, have suggested that most viruses that infect humans today may be at most one million years (my) old. Human RNA viruses would even be much younger than that and be characterized by extremely fast mutation rates. On the other hand, several authors have tried to trace back the origin of all viruses by comparing the secondary structure of bacterial and eukaryotic virus proteins. Based on these comparisons, a consensus has emerged suggesting that viruses are likely very old, probably as old or even older than cellular organisms, that is, more than 1 billion years old. According to this view, viruses would have even played a major role in the origin and evolution of cellular organisms. Between the very recent time scale of extant virus evolution and the very ancient origin of viruses, our understanding of the mode and tempo of virus evolution, including the antiquity of the families to which extant viruses belong, have long remained mysterious. The discovery of EVE is remarkable in this respect in that many EVE can be dated and used as molecular fossils to calibrate the origin and tempo of evolution of their cognate viral families.

Several dating approaches can be used to infer the age of EVE (Fig. 2). The first one is specific to retroviruses, which upon integration into the host genome generate identical repeated sequences on both sides of their genome, called long terminal repeats (LTR). Since mutations accumulate in each LTR at the mutation rate of the host, the age of a given retroviral EVE can be calculated by counting mutations that differentiate the two LTR of this EVE and dividing this number by two and by the mutation rate of the host. The second approach can be applied to all types of viruses. It relies on assessing the taxonomic distribution of a given EVE within the host lineage. The chances for a virus to integrate exactly the same portion of its genome exactly at the same genomic locus independently in two host lineages are extremely low. Therefore, finding a given EVE shared at the same genomic locus by two host species strongly suggests that endogenisation of this EVE took place in an ancestor of the two species (Fig. 2). If the time at which the two species diverged has been calculated, based on geological fossils for example, then one can infer that the age of the EVE is at least as old as this divergence time. Finally, one can also assign a relative age to a given EVE when this EVE has been hit by a TE. Since landing of the TE inside the EVE can only have taken place after the EVE entered the host genome, it is possible to infer that the EVE is older than the TE. If the time at which the TE has landed into the EVE can be calculated, based on comparison with other TE copies found in the host genome for example, then one can assign a minimal absolute age to the EVE.

The dating of EVE related to extant viral families can yield new, unique information that can be used in various ways (Fig. 3). For example, when a dated EVE falls within the diversity of an extant viral family, then the age of the entire family can be inferred to be at least as old as that of the EVE. This approach has led to drastic shifts in our perception of the time scale over which current viral lineages have evolved, showing that many viral families are much older than previously thought. For example, EVE belonging to the Circoviridae family have been found at the same genomic locus in the dog and the cat, which have diverged more than 50 my ago. This finding directly indicates that this family of small single-stranded DNA viruses is more than 50 my old, which sharply contrasts with the age of about 500 years which had previously been inferred for the origin of circoviruses currently circulating in pigs and birds. Similarly, while it was thought that Hepadnaviridae were at most 30 thousand years old, the discovery of endogenous hepadnaviruses shared between turtle lineages that diverged more than 200 my ago suggests that these viruses have co-evolved with amniotes since the beginning of the Mesozoic. The age of an EVE can also be used to calibrate the phylogeny of a viral lineage in order to estimate the age of the other nodes of this phylogeny. For example, the age of endogenous viruses related to nudiviruses found in the genomes of some parasitoid wasps has been used to infer divergence times among insect large double-stranded DNA viruses. The approach yielded an age of about 310 my for the origin of these viruses, suggesting that the first insects, which appeared at the end of the Devonian and beginning of the Carboniferous, were already infected by this type of viruses.

It is also possible to use EVE to study the evolutionary dynamics of viral lineages over timescales much larger than when including only circulating viruses in the analysis. For example, long-term viral substitution rates can be calculated on the branches separating an EVE from its closest circulating virus by counting the number of mutations that occurred on these branches, removing those that occurred on the EVE branch after endogenisation and dividing the remaining number of mutations by the time separating the EVE from circulating viruses (i.e., the age of the EVE). Such an approach has shown that viral substitution rates calculated over several dozens of my were several orders of magnitude slower than those calculated based only on currently circulating viruses. The discrepancy between substitution rates calculated over short and long timescales is particularly strong for viruses but it is also observed in cellular organisms. A large part of it can be explained by methodological limitations linked to the calculation of rates, both on short and long timescales. Importantly, it shows that rates calculated over different timescales depict different biological processes and that a rate calculated over a given timescale cannot be used to extrapolate the evolutionary dynamics of a viral lineage to a different timescale.

Fig. 2 Dating endogenous viruses. (A) Endogenous retroviruses can be dated by dividing the genetic distance (d) calculated between their two long terminal repeats (LTR) by 2 and by the host substitution rate. This is because when a retrovirus integrates, its two LTR are identical. The number of mutations differentiating the two LTR at any given time is proportional to the time since endogenisation. (B) All endogenous viruses (EVE) can be dated by searching for orthologous EVE copies in species other than the one in which they have been first identified. In this example, an endogenous hepadnavirus has been identified at the same orthologous locus in four turtles (+) and this EVE is absent from two crocodile species. Divergence times between turtles are known so it is possible to infer that the EVE is at least as old as the ancestor of the four turtles (200 my old). This age contrasts sharply with the age inferred for viruses currently circulating in mammals and birds.

Evolutionary Impact of Endogenous Retroviruses

The presence of many EVE in the genome of eukaryotes begs the question of the fate of these sequences, as well as of the impact they may have on the evolution of their host. Most of what we know about these questions can be drawn from the studies of vertebrate retroviruses, which are both the most numerous and most studied EVE. After endogenisation, some copies of endogenous retroviruses can be transcribed and generate new copies in the host genome. The increase in copy number can occur either through retrotransposition in germline cells, a process that does not involve the formation of infectious viral particles, or through reinfection of germline cells by infectious viral particles produced by endogenised copies. About half of the endogenous retrovirus copies found today in the genome of vertebrates are old, degraded and unable to produce proteins involved in viral replication. Yet, several recent integrations of retroviruses able to produce new copies have been described in various species. For example, the genome of the mouse contains several thousands of an endogenous retrovirus called IAP (Intracisternal A Particle), among which hundreds are still able to duplicate via retrotransposition. In koalas, a circulating retrovirus called KoRV is currently invading the genome of some populations located in northern Australia, while southern populations are completely devoid of the virus. Copies of KoRV have been dated at less than 50,000 years, but it is unknown whether they are transcribed and able to generate infectious particles. In human, a study published in 2015 has shown that copies of the most recently endogenised retrovirus (HERVK) constitutively produce viral particles during early embryonic stages. The function of these particles, if any, remains to be elucidated. While it is possible that they may simply be relics of benign infections without any detrimental effect, they may also be involved in the priming of the immune system which is essential during early embryonic development.

Fig. 3 Phylogenetic position of endogenous viruses and age of cognate viral families. (A) In this tree, endogenous 40 my old circoviruses fall outside of the clade containing all modern members of the *Circoviridae*. Thus the age of endogenous circoviruses does not inform us on the age of extant ones. In (B), endogenous circoviruses fall within the diversity of extant *Circoviridae* such that it is possible to infer that the ancestor of all known circoviruses is at least as old as the age of endogenous circoviruses, that is, 40 my old.

The presence of multiple copies of endogenous retroviruses in the genomes of vertebrates can have multiple negative consequences, whether these copies are still active or not. New copies generated by active EVEs can land within genes, affecting transcription or gene splicing and leading to the formation of defective mRNA. In addition, each endogenous retrovirus copy contains numerous regulatory elements necessary to recruit all the components of the transcription machinery. Integration of a new copy of endogenous retrovirus at a given locus can thus severely disturb the chromatin structure and the regulation of transcription in the vicinity of this locus. Host genes located within the affected region may be negatively impacted. In the mouse, it has been estimated that no less than 10% of all mutations inducing visible phenotypic consequences are due to new integrations of endogenous retroviruses that modify the regulation of neighboring genes. Another type of negative consequences endogenous retroviruses may have on their host genome is through mediating events of non-allelic homologous recombination between two identical copies located at different loci in the genome. Several human diseases are known to be the consequence of such rearrangements. For example, a deletion of 729 kb produced by homologous recombination between two copies of endogenous retroviruses located on the Y chromosome is associated to some forms of male sterility.

The impact of endogenous retroviruses on their host can also be positive. A large fraction of the genetic material added to vertebrate genomes by retrovirus endogenisation has indeed been recycled, or domesticated, and is now involved in multiple cellular functions. Numerous examples of human or mouse genes have been characterized for which transcription is initiated by a promoter derived from the LTR of an endogenous retrovirus copy. A number of studies have even shown that regulatory elements found in the LTR of some endogenous retroviruses have been recurrently domesticated and are now pivotal for the coordination of some gene regulatory networks, such as those involved in immune responses. Ironically, these EVE-derived regulatory sequences, which used to be essential for the virus to fulfill its replication cycle at the detriment of the host, are now involved in the adaptation of the host antiviral immune response.

The contribution of endogenous retroviruses to vertebrate genes at the protein level is less extensive, in terms of number of genes, than the contribution of EVE-derived regulatory elements. Yet, some domesticated viral proteins are now fulfilling major cellular functions that have probably been crucial to the evolutionary success of mammals. The first of these functions is the formation of a specific membrane of the placenta, called syncytiotrophoblast, which facilitates exchanges of nutrients, gases and other material between the mother and the embryo. Some of the key genes involved in the formation of this membrane have been acquired by mammals through domestication of the envelope gene of several endogenous retroviruses. Interestingly, domestication did not happen only once in the ancestor of all mammals, but repeatedly and independently on at least seven occasions during the evolution of mammals. Each of these domestication events, which took place in primates, rodents, rabbits, carnivores, ruminants, tenrecs and marsupials, involved a different copy of endogenous retrovirus, originating from distinct endogenisation events. The second function deriving from domestication of an endogenous retrovirus protein is linked to antiviral immunity. Several genes deriving from the envelope of specific copies of endogenous retroviruses have been characterized in cat, mouse and sheep, that provide immunity against currently circulating retroviruses. Circulating and endogenous retroviruses interact both with the same cellular receptors via the surface domain of their envelope protein. The regulated expression of domesticated endogenous envelope proteins interferes with the interaction between circulating infectious viruses and cell receptors, preventing viral entry into host cells.

Evolutionary Impact of Non-Retroviral EVE

Non-retroviral EVE are less numerous and have been less studied than retroviral EVE. While their global impact on eukaryotic genomes does not seem to be systematically as important as that of retroviral EVE, an increasing number of examples tend to show that non-retroviral EVE are not simply neutral passengers of eukaryotic genomes. In plants, for example, the recurrent endogenisation of florendoviruses, which are related to members of the *Caulimoviridae* family, produced a large number of copies in the genome of several species such as grapevine, rice, banana, *Petunia* or tomato, reaching 1.3% of the total genome size in the castor bean (*Ricinus communis*). It has also been shown that the expression of some copies of these endogenous florendoviruses could be induced by several types of stresses, including wound, heat or hybridization, ultimately leading to the production of infectious viral particles. In human, we know that the HHV6 herpesvirus is able to integrate its genome into the telomeric regions of several chromosomes and that it can be vertically transmitted from parents to their children. It has been estimated that about 0.5% of the human population bears at least one copy of endogenous HHV6 that can be activated and form infectious viral particles under various types of stressful circumstances. Some evidence even exists supporting a link between the presence of endogenous HHV6 and the development of angina pectoris.

Much like what has been observed for endogenous retroviruses, some non-retroviral EVE have been domesticated by their host and are now fulfilling crucial cellular functions. One of the most spectacular example of domesticated non-retroviral EVE is found in parasitoid wasps. Most parasitoid wasps (Hymenoptera, Ichneumonoidea) are koinobionts, meaning that their larval development takes place inside the arthropod hosts they parasitize, which remain alive until the wasps enter the nymphosis stage. Several wasp families have domesticated EVE-derived genes, which allow them to produce virus-like particles that they inject together with their eggs into host larvae. These particles contain virulence factors (circular wasp DNAs and/or wasp proteins) which decrease the intensity of the host immune response and facilitate the development of wasp larvae. The EVE from which wasp domesticated viral particles derive result from multiple events of endogenisation of large double stranded DNA viruses that took place at different time points and in several branches of the wasp phylogeny. It is likely that these endogenisation events, one of which has been dated at 100 my ago, have been pivotal for the evolutionary success of wasps.

A beneficial role of non-retroviral EVE linked to antiviral immunity is also suspected in an increasing number of cases. The way EVE-derived antiviral immunity is thought to occur is via the production of EVE-derived small RNA that trigger RNAi mediated recognition and destruction of cognate circulating viral RNA genomes and/or transcripts. In the tiger mosquito for example, no less than 472 EVE have been identified, deriving from 8 viral families. Mapping of small RNA libraries on the mosquito genome revealed that many EVE produce piRNA, a type of small RNA that, among other roles, are involved in controlling the activity of TE. While a definitive demonstration of the antiviral role of EVE-derived piRNA is still lacking, such piRNA have been identified in a large number of other species such as plants, many other insects, ticks and rodents. Based on these and other findings, a general model of EVE-derived antiviral immunity has been proposed which posits that repeated viral assault of a given host lineage might be accompanied by recurrent birth and death cycles of domesticated immunity-conferring EVE. This model predicts that when the antiviral activity of a given EVE becomes obsolete, either because the host is no longer exposed to the virus, or the host has become tolerant, or the virus has gone extinct, the EVE may either slowly decay by accumulating mutations or it may be co-opted to perform a new cellular function.

Ecology of Host-Virus Interactions

Our understanding of host-virus interactions has long been biased by the methodological limitations preventing us from discovering non-pathogenic viruses. Today, we know that viruses are the most numerous organisms on the planet, that they make up the largest and most diversified gene reservoir, and that they play key roles in ecosystem functioning. For example, viruses contribute substantially to carbon cycling through their decay and the pressure they exert on marine microbial communities. It is becoming clear that viruses are ubiquitous both in the environment and in cellular organisms and that they can no longer be only considered as pathogenic organisms having deleterious consequences on their hosts. Indeed, some plant and insect viruses are regularly discovered that are beneficial to their host, either by boosting their immune system, by allowing them to produce higher numbers of offspring, or even allowing them to colonize new ecological niches.

A large fraction of our new perception of the place viruses occupy in ecosystems derives from the development of viral metagenomics, a technique allowing to sequence the genomes of all viruses present at a given time in a given environment without having to isolate and cultivate them. Much like viral metagenomics, paleovirology offers a new way to discover and study viruses without a priori suspicion of their presence based on pathological symptoms. Just by discovering an EVE in a given host, one can deduce that the circulating virus from which the EVE derives was infecting this host, that the cellular tropism of this virus included germline cells and that the virulence of this virus was low enough for the host to survive, ensuring vertical transmission of the EVE via reproduction. Many EVE have been discovered in the genomes of species that are not known to be infected by cognate circulating viruses today. It is true for hepadnaviruses, for example, which were found endogenised in the genomes of passerine birds, snakes, turtles and crocodiles. Endogenous lentiviruses have been found in the genome of various mammals (e.g., rabbits and hares, malagasy lemurs, dermopterans) in which related circulating viruses have never been found. Whether these species are no longer infected by these viruses or whether they are still infected but we have so far not been able to detect such circulating viruses is an open question. Given the role some EVE play in thwarting cognate circulating viruses, one could expect a link between

the presence of EVE in a given species and the absence of cognate circulating viruses, or at least the absence of pathology induced by such viruses, rendering them difficult to detect.

The combination of approaches such as viral metagenomics and paleovirology holds great promise in furthering our understanding of host-virus interactions. Sometimes, however, paleovirology by itself offers unique opportunities to shed light into long-held conundrums. For example, the discovery of EVE in the genome of an algae species (*Bigelowiella natans*; Rhizaria) helped deciphering the intriguing relationships between giant viruses, viruses infecting these giant viruses (called virophages), and unicellular eukaryotes infected by giant viruses. The Sputnik virus, discovered in 2008, was the first to be classified in the new category of viruses parasitizing other viruses called virophages because of its inhibitory effect on the replication of giant viruses belonging to the putative “Megavirales” order. Since then, other virophages have been characterized and it has been proposed that eukaryotic TE belonging to the Maverick/Polinton group derive from ancient virophages that have acquired the capacity to integrate into and transpose within eukaryotic genomes. The discovery of intact virophage genomes in the genome of *B. natans* (called provirophages) was thus remarkable in this context, as it provided strong support for the evolutionary link between these viruses and Maverick/Polinton TE. Interestingly, the study performed in *B. natans* also characterized genes derived from giant viruses endogenised in the *B. natans* genome and showed that many provirophage genes were transcribed. The results thus confirmed that virophages and giant viruses can co-exist in *B. natans* cells and they suggest that endogenisation of virophages could be beneficial not only to the virophage itself but also to its host. Being integrated and transcribed in the genome of its host, the virophage increases its chances to encounter the giant viruses it replicates on, and by parasitizing these viruses, the virophage offers protection against giant viruses to the algae. More recently, another elegant study combining paleovirology and experimental assays verified the predictions formulated in the *B. natans* study, which were based only on a paleovirological approach. This second study showed that the Mavirus virophage is able to integrate at multiple sites into the genome of its host, the marine protozoan *Cafeteria roenbergensis*. The genes encoded by integrated virophages are specifically activated when the host is infected by a giant virus called CroV (*Cafeteria roenbergensis* virus). Remarkably, it was demonstrated that the virophage particles released by infected cells are able to suppress CroV replication in other cells, thus offering an antiviral protection to the protozoan.

Other Contributions of Paleovirology to Our Understanding of Host-Virus Interactions

Paleovirology has contributed to bolster our understanding of long-term host-virus interactions in a number of ways other than those already exposed in the preceding sections. For example, several research groups have successfully attempted to reconstruct portions or even fully functional and infectious versions of ancient retroviruses using a collection of endogenous retroviral sequences. The resurrection of ancient primate retroviruses such as HERK found in human and CERV1 and CERV2 found in chimpanzee showed that these viruses were unlikely targeted by TRIM5 α , a primate restriction factor known today to provide immunity against various modern retroviruses. On the contrary, the replication of these ancient viruses was shown to be actively repressed by mRNA editing through APOBEC3G, another restriction factor which has been shown to evolve under constant purifying selection during primate evolution. It has even been possible to reconstruct the crystal structures of the capsid proteins of two prehistoric lentiviruses identified in rabbits and Malagasy primates that are respectively about 12 and 4 my old. These studies revealed a remarkable structural conservation between ancient and modern lentiviruses despite a very low level of primary sequence identity. They also showed that interaction between the capsids of modern lentiviruses and the host factor cyclophilin A, known to be essential for extant lentiviruses to be infectious, already existed at the time at which the two reconstructed lentiviruses were infecting mammals.

A lot can be learnt on the long-term evolutionary arms races that have been taking place between viruses and their hosts not only by studying EVE but also through the inference of the forces that have governed the evolution of host restriction factors. Viruses and their hosts are often caught in a cycle of adaptation/counter-defense whereby the virus constantly finds ways to thwart host immune strategies. Such dynamics translates in a high rate of amino acid change in some regions of the viral genome, driven by positive selection. After reconstructing the phylogenetic tree of a given restriction factor, it is possible to assess which part of the evolutionary history of this factor has been characterized by intense battles with some viruses by mapping inferred ratios of synonymous versus non-synonymous substitution rates on each branch of the tree. Such studies have not only revealed that extant primate restriction factors were shaped by long-lasting conflicts with viruses, they also helped to pinpoint which protein domains of these factors were at the very interface of these conflicts.

Finally, the study of EVE offers unique opportunities to understand how the structure of modern viral genomes has evolved. In particular, EVE may allow us to decipher what mechanisms underlie the birth of new viral accessory genes, which has often remained mysterious. For example, the finding that an accessory gene lying between the pol and env genes of an ancient primate lentivirus was similar to the 3' end of the reverse-transcriptase (RT) domain of this virus suggested that the accessory gene might have arisen through duplication of a fraction of the RT gene. While none of the known accessory genes of modern retroviruses are similar to any other protein domain encoded by their respective viral genome, it is possible that at least some of them first emerged through such duplication and later lost any trace of their origin because of the numerous mutations they accumulated. The characterization of ancient hepadnaviruses also allowed to untangle the origin of the X gene found in mammalian orthohepadnaviruses and known to be involved in the formation of tumors in chronic infection by these viruses. An X-like gene has been characterized in some bird avihepadnaviruses suggesting that the birth of the X gene may predate the split between bird and mammal hepadnaviruses. Yet, the absence of this gene in all endogenous bird hepadnaviruses, coupled to the different genomic

location of the X-like gene and X gene have challenged this view. Much like what has been inferred for the origin of lentiviral accessory genes, a fine dissection of the structure of endogenous and exogenous hepadnaviruses led to the conclusion that the X gene evolved in the ancestor of orthohepadnaviruses, after the split between mammalian and bird hepadnaviruses, likely through segmental duplication of the viral genome.

dsRNA double-stranded RNA

ssDNA single-stranded DNA

(+)ssRNA positive-sense single-stranded RNA

(-)ssRNA negative-sense single-stranded RNA

Glossary

Analogy Similarity observed between traits that arose independently in different lineages and that resulted from convergent evolution. Also termed coincidence.

Fusogen Any substance that mediates the fusion of two biological membranes.

Homology Similarity observed between traits that descended from a common ancestor by divergent evolution.

Horizontal gene transfer The exchange of genes between organisms of the same or different species, or between

organisms and viruses, in contrast to vertical gene transfer in which parental genes are inherited by progeny.

Jelly-roll A protein fold composed of eight β strands arranged in two four-stranded sheets ("double β -barrel" and "double jelly-roll" are used here as synonyms).

Phylogenetics The study of how epidemiological, immunological, and evolutionary processes act and potentially interact to shape viral phylogenies.

Virosphere The ensemble of all viruses that populate the Earth.

The Evolution of Viruses

Viruses permeate the entire biosphere and are by far the most abundant biological entities, outnumbering all cellular organisms in the biosphere ten-fold. A recognition of their evolutionary relationships helps us to understand how viral infections impact host populations. Moreover, untangling the complexity of viral diversity is an essential component of the human effort to comprehend the natural phenomena of which we are a part.

The raw materials for viral evolution are the heritable genetic changes that viral genomes accumulate during the virus life cycles. The maintenance of these changes in the viral population can be an adaptive response to environmental pressures, pressures that include antiviral pharmacological therapies and the host's immune response. Without such adaptation, that virus would disappear. Viruses

Fig. 1 Estimation of mutation rates in viruses, viroids, and cellular organisms. Diagram plotting the per-site mutation rate against the genome size of various entities: (1) a viroid (*Chrysanthemum chlorotic mottle*); (2) RNA viruses (tobacco mosaic virus, human rhinovirus, poliovirus, vesicular stomatitis virus, bacteriophage $\Phi 6$, and measles virus); (3) ssDNA viruses (bacteriophage $\Phi X174$ and bacteriophage m13); (4) dsDNA viruses (bacteriophage λ , herpes simplex virus, bacteriophage T2, and bacteriophage T4); (5) bacteria (*Escherichia coli*); (6) lower eukaryotes (*Saccharomyces cerevisiae* and *Neurospora crassa*); higher eukaryotes (*Caenorhabditis elegans*, *Drosophila melanogaster*, *Mus musculus*, and *Homo sapiens*). evolve rapidly (**Fig. 1**), so rapidly that evidence of inherited similarity in viral genomes can be obscured, or even lost entirely. Inherited traits with major consequences for the virus life cycle and structure may persist longer than others and therefore provide a more powerful means of assessing viral evolutionary relationships. Even with this approach, the making of such assessments is a complex challenge that draws upon numerous diverse, yet complementary, disciplines including virology, epidemiology, computational biology, genomics, structural biology, evolutionary biology, and others.

When studying the origin and evolution of cellular organisms, the genes encoding ribosomal proteins, which are present in all organisms, have been used as genetic fossils that preserve a record of evolutionary history. Not only do viruses not have ribosomes, but there is no other gene that is present in all viruses. Possible similar universal hallmarks that could be used to infer evolutionary relationships among viruses are still under intense debate. The emerging concept of viruses as “capsid-encoding organisms” underlines that all of these entities need to couple the genetic information for a replicon (nucleic acid capable of autonomous replication) with that for a capsid to produce a virion. This definition is in line with the notion proposed a few years ago by Bamford, Burnett, and Stuart that each virus has an innate “self” which is constituted by structural and functional traits that recapitulate the virion architecture and the major components of the virion. This concept has been applied to viral classification and phylogeny through the analysis of the conformational space adopted by the major capsid proteins (MCPs).

The description of viruses as “capsid-encoding organisms” attempts to draw a parallelism with the definition of cells as “ribosome-encoding organisms”. In so doing, the denigration of viruses as pickpockets of cellular genes fades and is replaced by appreciation of the intricate relationships between viruses and their host cells. These relationships and the capacity of viruses to subvert cellular functions for the production of their virions have led some to wonder whether viruses should be considered to be alive. While viruses remain parasitic entities, their evolution is tightly linked to cellular evolution and the origin of Life, and vice versa. Even a minimal understanding of their evolution demonstrates their impact on several areas of importance ranging from host-virus co-evolution to virus-mediated cross-species transmission, as well as vaccine escape, the evolution and spread of resistance of anti-viral drugs, and so on.

To help organize the known viruses – a small part of the entire virosphere – a hierarchical taxonomic system has been widely used. This classification system, which is based mainly on similarities at the genome level and in virion morphology, groups the viruses by order, family, genus, and species, and more recently expanded to include higher-level taxonomic ranks of class, phylum, kingdom and realm (equivalent to the domain rank for cellular organisms). Another virus classification scheme that has also persisted was proposed by Baltimore in 1971, which groups viruses based on their genome’s molecular structure and replication mechanism. This yielded five groups with straightforward replication of dsDNA, ssDNA, dsRNA, (+)ssRNA, and (–)ssRNA genomes. Two additional groups utilize reverse transcriptase in replication, one of which replicates their ssRNA genome via a DNA intermediate, while the other replicates dsDNA genomes via an RNA intermediate. Currently, the ICTV taxonomy system employs the information available about the viral genome combined with the virus’s cellular host (animal, plant, fungus, bacterium, or archaeon). Although this approach tries to utilize the sheer wealth of data coming from recent viral nucleotide sequencing projects to make sense of the vast viral diversity, viral classification on this basis becomes difficult when sequence similarity at genomic (and protein) level is questionable or has been lost over time.

Thus, some of the basic questions underlying the concept of viral evolution are: First, what tools do we have in our hands to decipher viral evolution? And second, how far can our tools trace viral phylogenies?

In the following sections, I will succinctly touch on some of the tools and viral traits that have been employed in efforts to understand the virosphere and its evolutionary history.

Viral Evolutionary Relationships From Sequence Analysis

When we compare two genes or proteins, the higher the percentage of sequence similarity between them, the lower the probability that they have originated independently. On this basis, we can infer that highly similar sequences are homologous, i.e., that they descended from a common ancestor (homology; divergent evolution). However, this interpretation based on high sequence similarity cannot exclude an alternative scenario driven by convergent evolution (analogy or coincidence); for an elegant explanation of the two different evolutionary scenarios, please see [Koonin and Galperin \(2003\)](#) in Further Reading. Viruses evolve fast (**Fig. 1**). As a result, sequence similarity assessed at the genomic (DNA or RNA) or protein level is quickly lost. Valid inference of common ancestry among viruses requires application of other criteria beyond the single number representing the sequence similarity. The diverse viruses assemble virions that are of different shapes and sizes, and that encapsulate genomes of different types that were replicated by different mechanisms. These, too, are inherited traits whose similarities can also be considered.

Cheaper and more powerful computing, combined with the explosion of viral genomics and metagenomics, has accelerated extensive sequence analysis which, in turn, has established viral relationships that were previously unnoticeable. Analysis of viral sequences has led to two important outcomes, among others: (1) the ability to group viruses in lineages based on sequences of cardinal viral genes/proteins; and (2) the establishment of phylodynamics, a field that draws upon multiple disciplines including epidemiology and evolutionary virology.

When applying the usual distance-based methods of sequence analysis, one must choose whether to compare entire genomes or only selected parts. Whole genome comparisons can be misleading when tracing the evolutionary history of viruses. Careful selection of subgenomic regions for comparison can be more appropriate to this purpose (see below). Another fundamental issue when establishing viral evolutionary relationships from sequence analysis is how to define the minimal similarity threshold required for

two sequences to be recognized as similar. The appropriate threshold depends on the sensitivity of our tools for detection, as well as on the further constraints applied by the sequence alignment strategies and algorithms employed. These constraints may include the position of the sequence within the genome, conserved mutations, frequencies of appearance, and/or any relevant biological information available.

Wise selection of genes for comparison must take into account the eventuality of horizontal gene transfer between viruses and the corresponding hosts. One result of these transfers is that viral genomes can contain modules with different evolutionary histories. To minimize this potential source of error we are obliged to select genes that are more likely to be transferred vertically rather than horizontally. Horizontal gene transfer with the host, for example, can bias an analysis and yield erroneous viral groupings. Of course, a wise assessment demands that the biological function of the genes being considered for analysis must be known. In fact, accurate analysis is even more challenging. Whether considering a gene or a protein, the analysis is limited to comparisons made between primary sequence(s), i.e., between two strings of letters representing bases or amino acids. Each of these one-dimensional strings encodes three-dimensional spatial information and function, neither of which can be decoded from the sequence *a priori*.

Koonin and colleagues have profitably classified viruses using specific viral hallmark genes such as the one that encodes the RNA-dependent RNA polymerase (RdRp) enzyme (Fig. 2). This enzyme catalyzes the synthesis of RNA from an RNA template and is unique to RNA viruses that must replicate the viral genomic RNA. This viral group includes the majority of viruses that infect eukaryotes. Comparative analysis of RdRp sequences has been used to classify these viruses as well as to address their origins. This approach led, for example, to the proposal that the picorna-like superfamily possesses a monophyletic origin. Initially, this sparked some debate about the adequacy of selecting a single gene to represent virus identity as opposed to the structure-based approach that uses the viral capsid fold as a “fingerprint” for mapping viral phylogeny (see below).

Fig. 2 Phylogenetic tree of RNA viruses using RNA-dependent RNA polymerase (RdRps) and reverse transcriptase (RTs) sequences. The different colors highlight the five main branches emerging from the iterative clustering-alignment-phylogeny procedure. Branch-1: leviviruses and their eukaryotic relatives; Branch-2: (+)ssRNA and dsRNA viruses of eukaryotes; Branch-3: distinct subset of (+)ssRNA viruses; Branch-4: dsRNA viruses; Branch-5: (–)ssRNA viruses. A set of RTs from group II introns and non-long-terminal-repeat (non-LTR) retrotransposons was used as an outgroup. Reproduced and adapted with permission from Wolf, Y.I., Kazlauskas, D., Iranzo, J., *et al.*, 2018. Origins and evolution of the global RNA virome. *mBio* 9.

This apparent conceptual and methodological dichotomy is soon resolved by defining a virus as a replicon capable of producing a virion. Within this framework, both approaches manifest strengths and limitations as tools for virus classification. Viral sequence analysis has proven itself to be a powerful means to establish relatedness between genes/proteins and, importantly, to trace the complex intertwined evolutionary relationship between viruses and cellular organisms. Further, the power of comparative viral genomics can also be used to rein in virus emergence. Virus genome sequences paired with their geographical distribution allows prediction of the rise of novel strains or species and also establishment of a molecular clock for the spread of different strains. Although this is not, strictly speaking, the assessment of common ancestry, nevertheless, the predictive power of phylodynamics over short evolutionary time is indisputable. Already it has served to infer spatiotemporal information during the diffusion of the HIV, Ebola, and Zika viruses, among others.

In addition to the viral genomic data, there is an immense amount of metagenomic information currently available thanks to the increased speed and lower cost of high-throughput sequencing. Viral metagenomics retrieves sequences directly from an environment without knowing a priori whether they are derived from viruses, viral hosts, or other sources. Comparison of these metagenomic libraries against known and assigned genome sequences can sometimes reveal both sequence source and function. For sequences from cellular organisms, the source can be identified based on the sequence of the ribosomal genes that all organisms possess. No such universal fingerprint gene exists for viruses. Despite this difficulty, viral metagenomics offers a unique window into viral communities and their ecological niches. It also can help decipher viral phylogeny provided the distance-based tools are sensitive enough to identify at least those viral genetic traits that are less susceptible to the passage of time. Given this wealth of genomic and metagenomic sequence data, the question arises whether it should be integrated into virus taxonomic classification and, if so, how.

A Change of Paradigm: Structure-Based Virus Classification

Comparative analysis of viral proteins based on their primary sequence is limited to comparison of monodimensional arrays of twenty letters, each letter identifying one of the twenty common amino acids. By contrast, comparison of three-dimensional (3D) protein structures captures increased complexity. In the eighties, structural analyses of plant and animal-infecting viruses of the *Picornaviridae* family revealed similarities in the corresponding MCP folds despite their lack of sequence similarity. These MCPs possessed single β -barrels arranged with the long axis of the β -barrel tangential to the virus surface. At the time, the dearth of available virus structures made it impossible to determine whether the detected similarities were the remains of an ancestral relationship or were the result of structural necessity, being the only way to form a suitable viral capsid.

With further research came the realization that the capsid protein fold and the arrangement of protein subunits within the capsid can be preserved over evolutionary time. Thus preserved, the same ancient structures can be found today even in viruses that belong to different taxonomic families and that infect divergent hosts. Pivotal here was the determination of the structure of the MCP of the enteric, membrane-containing bacteriophage PRD1 (family *Tectiviridae*) by X-ray crystallography. Strikingly, it was found that the PRD1 MCP possessed the so-called double β -barrel fold (or double jelly-roll fold) equivalent to the human adenovirus hexon MCP (Uniprot code P03277) with which it was superimposable with 3.6 Å rmsd [192 C α s aligned between PRD1 P3 (PDB 1HX6) and adenovirus hexon (PDB 1P30)], but with which it shared only 12.5% sequence similarity (8.3% sequence identity) in a pairwise sequence alignment. This, in conjunction with the initial cryo-electron microscopy (cryo-EM) studies of PRD1, made it clear that both PRD1 MCP P3 and the adenovirus hexon were arranged in similar trimers, with the long axis of the β -barrels orthogonal to the virus surface, to form pseudo-hexagonal capsomer structures. Both viruses displayed the same triangulation number: pseudo- $T = 25$.

This emerging concept that structure was preserved longer than sequence similarity suggested a possible method for demonstrating even more distant evolutionary relationships across diverse viruses. More evidence of this was soon obtained. Simple manual fitting of the four P3 capsomers making up for the PRD1 icosahedral asymmetric unit into the low-resolution 3D cryo-EM derived map of the large chlorella virus PBCV-1 (1,900 Å diameter) (family *Phycodnaviridae*) by Bamford and colleagues supported the hypothesis that PBCV-1 belonged to the same lineage as PRD1 and adenovirus. This hypothesis was then experimentally proven when the Rossmann Lab determined the crystal structure of the PBCV-1 MCP Vp54 and found that it, too, displayed a double jelly-roll fold. Use of the conservation of MCP folds to classify viruses beyond short-distance relationships not only prompted vigorous debate, but also further fuelled the systematic biochemical and structural study of these viral proteins and novel viruses.

Conceptualization of a structure-based viral phylogeny took another step forward with the determination of the crystal structure of the whole PRD1 virus to 4.2 Å resolution. To the compelling structural equivalences in the MCP fold was now added similarity in the architectural building principles of larger viruses such as adenovirus. These observations provided the foundation for definition of the PRD1-adenovirus lineage. In the course of time, bacteriophage PRD1 has turned out to be a remarkable model system for studying important viral processes in lipid-containing viruses. Its structure made clear the virion assembly pathway and also offered a unique scalable mechanism for determining particle size by using a molecular tape measure (see [Abrescia et al., 2004](#) in Further Reading).

However, the concept of the MCP as the defining ‘viral self’ structure, based as it was on comparison of 3D atomic models, led inevitably to debate about homology versus analogy (for a deeper discussion of this topic, I direct the more curious reader to the Further Reading section). When using a structure-based approach in virus classification one must keep in mind that a virus not only has to build a virion, but also to package its genome within. The packaging mechanism, in turn, is tightly linked to how the genome-containing safe box, the capsid shell, is constructed. Therefore, if similarity of the “self” characters (MCP folds and assembly principles) leaves doubts as to the relatedness of two viruses and further constraints are needed, the genome encapsidation mechanism is the next criterion in line. If doubts still remain, comparisons should be made on a case-by-case basis.

During the past fifteen years, structures of several more viral MCPs and viruses have been determined by different laboratories around the world. This deeper sampling of viral MCP folds, in conjunction with structural comparisons between them all, showed that (so far) many of the viral families within the viral universe can be classified into four lineages: the PRD1-adenovirus lineage, the HK97 lineage (comprising the largest number of representatives), the BTV-lineage, and the picorna-like lineage (Fig. 3). Inevitably, the complexity of ordering the viral universe through this structure-based approach will require constant revisiting of the work done until now, particularly when more viral structures emerge. Unanswered questions still remain. For example, enveloped viruses, for which a consensus “self” has not yet been identified, remain unclassified so far. Moving forward now calls for more viral structures at atomic resolution to deepen and extend the comparisons across different virus families.

Cryo-EM is supplementing X-ray crystallography now more and more thanks to its capability to provide high-resolution (HR) imaging. Recent examples of its usefulness include the structure determination of plant filamentous viruses and the elucidation of the assembly mechanism of viruses whose MCPs contain two vertical single β -barrels. In the former, the cryo-EM structure of helical plant viruses with (+)ssRNA belonging to the *Alphaflexiviridae* and *Potyviridae* families at 3.9 Å resolution unexpectedly revealed that their MCPs are structurally similar to the nucleoprotein of certain non-segmented (–)ssRNA enveloped animal-infecting viruses of the *Bunyaviridae* and *Orthomyxoviridae* families. This observation could be interpreted as evidence that the MCP of these plant viruses was transferred to the animal kingdom and there hijacked for use as a chromosome condensing agent that later, over evolutionary time, acquired a membrane envelope. Should we conclude that these plant and animal viruses share common ancestry? Caution should be used in this case. While the structural homology of the corresponding MCP and nucleoprotein is apparent, no other traits are shared between those viruses, e.g., pepino mosaic virus *versus* Rift Valley Fever virus. This fact undermines the hypothesis of their common descent, but does evidence a possible gene transfer between the plant and animal kingdoms.

In the case of vertical single β -barrel viruses belonging to the *Sphaerolipoviridae* family, the discovery that different viruses using two MCPs displayed capsomers with a pseudo-hexameric footprint but with a distinct number of protruding turrets (even within the same icosahedral asymmetric unit) challenged the known assembly mechanisms. Cryo-EM of whole virions at 3.7 Å resolution showed that the two vertical single β -barrel MCPs (one of which turreted) formed heterodimers that assembled as pseudo-hexameric capsomers to form the capsid shell. This step relies on two proteins with different folds located proximal to the membrane vesicle, as well as on the organizing membrane protein complex at the vertices. The individual vertical single β -barrels whose hetero-dimerization replicates the double β -barrel MCP, can be structurally classified as clade within the vertical double β -barrel PRD1-adenovirus lineage (Fig. 4). Most importantly, determination of these virus structures has revealed how the fusion during evolution of the two vertical single jelly-roll MCPs led to the assembly of membrane-less members of the PRD1-adenovirus lineage such as adenovirus.

In conclusion, changes in the 3D structure seem to occur at a slower rate than do changes in the sequence, indicating that the sequence space is larger than the fold space. Possible folds of these proteins are more constrained by their function, while sequence similarity is more easily lost without loss of function during evolution. Therefore, similarity of viral sequences is a less reliable means for mapping distant viral phylogeny. A better tactic here is to compare the structures of viral “self” proteins (e.g., proteins involved in virion assembly and those coupled to the genome packaging processes) whose alteration might compromise the virus identity and/or the production of competent progeny. In this view, the structural-functional requirements placed on the viral “self” act as a biological constraint on evolutionary changes, thus “steering” evolution.

Inferring Viral Evolutionary Relationship Through Structure-Based Classification

Identifying homology in protein structures requires more than simply interrogating the virosphere. Development of tools for this next step and their refinement represents one of the ongoing challenges of modern biology.

To infer evolutionary relationships using the 3D structure of viral proteins entails four important concepts: (1) targeting the “correct” viral protein, i.e., one that reflects the invariant character of a virus (“self”) through evolution; (2) solution of the 3D structure of this viral protein; (3) development and application of “specific” tools for structural comparison; and (4) translation

Fig. 3 The virosphere and the representative MCP fold for each structure-based lineage. (Above) The International Committee on Taxonomy of Viruses (ICTV) scheme (adapted from the Universal Virus Database 2005) is shown with the currently defined orders and the virus families within each defined by letters. Families that in 2005 were not assigned to an order are drawn in black (*Adenoviridae*, *Arenaviridae*, *Ascoviridae*, *Asfarviridae*, *Astroviridae*, *Baculoviridae*, *Barnaviridae*, *Birnaviridae*, *Bromoviridae*, *Bunyaviridae*, *Caliciviridae*, *Caulimoviridae*, *Chrysoviridae*, *Circoviridae*, *Closteroviridae*, *Corticoviridae*, *Cystoviridae*, *Flaviviridae*, *Fuselloviridae*, *Geminiviridae*, *Guttaviridae*, *Hepadnaviridae*, *Hypoviridae*, *Inoviridae*, *Iridoviridae*, *Leviviridae*, *Lipothirixviridae*, *Luteoviridae*, *Metaviridae*, *Microviridae*, *Nanoviridae*, *Narnaviridae*, *Nimaviridae*, *Nodaviridae*, *Orthomyxoviridae*, *Papillomaviridae*, *Partitiviridae*, *Parvoviridae*, *Phycodnaviridae*, *Plasmaviridae*, *Polydnaviridae*, *Polyomaviridae*, *Potyviridae*, *Poxviridae*, *Pseudoviridae*, *Reoviridae*, *Retroviridae*, *Rudoviridae*, *Tectiviridae*, *Tetnaviridae*, *Togaviridae*, *Tombusviridae*, *Totiviridae*). (Below) MCP structure-based viral lineages mapped onto current ICTV taxonomy with each lineage colored differently. Individual viral families within each lineage are labeled and colored according to the key. Beneath that, representative ribbon diagrams depict the 3D structural models for each of the lineages. Structures are drawn to scale, colored in rainbow from the N-terminus (blue) to the C-terminus (red), and viewed as it would sit on the virion surface. Abbreviations: BTV, bluetongue virus (PDB ID 2BTV); PRD1/Adeno, PRD1/Adenovirus (PDB ID 2VVF); HK97, bacteriophage Hong Kong 97 (PDB ID 1OHG); Picorna, picornavirus (PDB ID 5NE4, VP2 subunit). Adapted with permission from Abrescia, N.G., Bamford, D.H., Grimes, J.M., Stuart, D.I., 2012. Structure unifies the viral universe. *Annual Review of Biochemistry* 81, 795–822.

of the result of a structural comparison into an evolutionary distance. Once the viral “self” has been identified or hypothesized (see previous sections), the limiting factor in ordering the viral universe through a structure-based approach is the availability of a sufficient pool of target proteins for which high resolution 3D structures have been determined.

With such a pool of structural data in hand, the next step is to employ this data in unraveling ancient viral evolutionary history. The fold of (viral) proteins is more than the manifestation in the three-dimensional space of the one-dimensional primary sequence. It is also the product of optimization of its biological function during evolution through the establishment of unique intra- and inter-molecular interactions. When molecular structures are available, their comparison has the power to make evident what constraints have been applied during evolution in order to maintain essential biological functions, even when similarity between the linear amino acid sequence appears to have been lost. This became apparent when the double β -barrel was found to be shared by the MCPs of membrane-containing bacteriophage PRD1 and adenovirus. With the viral MCPs we have proteins with a quintessential role in protecting the viral genome when outside the host cell. Their vital importance implied that a three-dimensional alteration could jeopardize the virus’s very existence. This, in turn, supported the hypothesis that in this case the structural similarity represented homology rather than a coincidental event. This view was later reinforced by the facts that virion architecture is, of necessity, coupled to genome packaging and that the genes for the capsid and for genome packaging often evolve together.

But how does one quantify the degree of the three-dimensional similarity when comparing viral ‘self’ proteins? The root-mean-square-deviation (rmsd) is one obvious measure. However, the choice of the method to be employed to structurally superimpose the two 3D atomic models constitutes an important decision as this will influence the meaningfulness of the resulting rmsd.

The Structural Homology Program (SHP), written by Stuart and colleagues and based on the technique developed by Argos and Rossmann, has been widely used for structural comparison of viral proteins. SHP is sensitive to “weak similarities” and relies on the probability of equivalence between alpha carbons (C α s) in pairwise structure comparisons. When comparing two proteins, designated A and B, the structure of protein A is rotated to explore all possible orientations about its center of mass. For each orientation relative to the structure of protein B, the probabilities of structural equivalence between the C α s are calculated. Specifically, these calculations for residues *i* and *j* in structures A and B take into account the closeness in space of their C α atoms and the local shape of the two polypeptide chains around these residues. This yields an estimate of the likelihood/probability (P_{*i,j*}) that these two residues (*i* and *j*) are structurally equivalent to each other. Once this has been estimated for all C α s, a matrix of P_{*i,j*} values for all *i* and *j* is built. The best path across this matrix is then defined as the one that fulfils the largest set of equivalences between A and B and maximizes the total probability, (Σ) P_{*i,j*}, for all residue pairs. From this an rmsd can also be produced for these two proteins (Fig. 5(a)).

At this point, having defined the total probability as an overall measure of the structural similarity of two proteins, the next step is to transform this probability into an evolutionary distance. In SHP the logarithm function is used for this transformation. The value of this function is 0 when its argument is 1; when the argument is less than 1, the value approaches minus infinity. Thus, if the probability of equivalence is 1, i.e., the structures are 100% equivalent (the same structure), then their evolutionary distance (D) is 0. Similarly, when the probability of equivalence approaches 0, the distance approaches infinity (there is a change in sign in the definition of D) (Fig. 5(a) and (b)). In this manner one can calculate the pairwise distances between various 3D protein structures and from this generate a distance matrix. This can then be fed into the PHYLIP phylogenetic analysis software package for transformation into a phylogenetic tree. A more exhaustive analysis of the classification methods based on 3D structures can be found elsewhere in the encyclopedia.

Fig. 4 Capsid organization of vertical single β -barrel MCPs and vertical double β -barrel MCP of the PRD1-adenovirus lineage. (a) Top, cryo-EM map at 3.7 Å resolution of *Haloarcula californica* icosahedral virus 1 (HCIV-1), a lipid-containing archaeal virus, pseudo-*T* = 28, color-coded by radius as indicated in key, with one virus facet delimited by white lines. Black pentagons, ovals, and triangle indicate the five-fold, two-fold, and three-fold axes of icosahedral symmetry, respectively. The white capsomers numbered from 1 to 3 yield a pseudo-hexameric, three-turreted morphology, while capsomer 4 and half-capsomer 5 (sitting on the two-fold axis of symmetry) yield a pseudo-hexameric, two-turreted morphology. Capsomers 1–5, together with one copy of the penton protein, compose the icosahedral asymmetric unit (IAU). Middle, schematic representation of the IAU with the arrangement of the individual MCPs depicted as circles (12 copies of turreted VP4 in blue and 15 copies of VP7 in gray) forming the differently-colored pseudo-hexameric capsomers, one copy of the penton protein VP9 as a black triangle, and the remaining four copies of VP9 sitting on the five-fold axis in dark gray. Bottom, tube representation of the individual vertical single β -barrel MCPs VP7 and VP4. Blue and red spheres denote the N-terminus and C-terminus, respectively. (b) Top, crystallographically-derived electron density at 7 Å resolution (slate-blue) of a member of the PRD1-adenovirus lineage: marine, lipid-containing bacteriophage PM2 (outer diameter 570 Å between icosahedral facets; pseudo-*T* = 21). One triangular virus facet is represented by the grey hexagons with on top triangles (coloured in yellow, green, cyan and blue) indicating, respectively, the displayed pseudo-hexameric morphology of the capsomers and the oligomerization state of the vertical double β -barrel MCP P2. The capsomers that compose the IAU are numbered from 1 to 4. Capsomer 4 sits on the icosahedral three-fold symmetry axis, red pentagons sit on the five-fold vertices, and the black ovals mark the two-fold axes of icosahedral symmetry. Middle, schematic representation of the IAU with the arrangement of the vertical double β -barrel MCP P2 depicted as pink dumbbells. Three copies of P2 form each of the pseudo-hexameric capsomers 1–3 and one copy forms capsomer 4 at the icosahedral three-fold axis (black triangle). The copy of the penton protein P1 participating in this IAU is depicted as a red triangle (with the remaining four copies of P1 sitting on the five-fold axis shown in dark-pink). Bottom, tube representation of the vertical double β -barrel P2 MCP with blue and red spheres indicating the N-terminus and C-terminus, respectively. (c) Superimposition of HCIV-1 MCP VP7-VP4 heterodimer (white-blue, 403 residues, PDB ID 6h9c), the building block for HCIV-1 capsomer assembly, onto the double β -barrel MCP P2 of bacteriophage PM2 (pink; 269 residues, PDB ID 2VVf), to yield a 4.2 Å rmsd with 189 C α equivalences. The relative angular orientation between the individual vertical HCIV-1 VP7-VP4 β -barrels practically replicates that of the double β -barrel MCP.

Fig. 5 Schematic representation of the concepts of structural equivalence and evolutionary distance. **(a)** Diagrammatic representation of a matrix of probabilities of equivalence calculated between two protein structures: A (green) and B (brick red). The i denotes the C α of residue i in A, while j denotes the C α of residue j in B. P_{ij} is the probability of equivalence for two given C α s, where $P\Delta_{ij}$ is a probability factor representing the distance between the two residues and PS_{ij} is a probability factor that represents the similarity of shape between the two chains in the regions surrounding residues i and j . The total probability ($P_{\text{tot}} = (\sum)P_{ij}$) defines the best 'path', i.e., the conformation that contains the largest set of correspondences and maximizes the sum of the individual probabilities. D is the evolutionary distance between the two structures (A and B) defined as the natural logarithm of the total probability minus two (the corresponding probability of equivalence of matching the N- and C-termini), normalized over the average numbers of C α s of A and B, N_{av} , with the removal of the N- and C-terminal C α s. **(b)** Properties of the logarithmic function that are exploited for the definition of the evolutionary distance (for visual clarity, this is shown for base 2 but holds for any base > 1). For the limiting case when $A = B$ (e.g., ribbon diagram of PM2 MCP P2 colored as a rainbow from blue N-terminus to red C-terminus), the argument of the logarithm is 1 and its result, the corresponding evolutionary distance D , is 0. When the two 3D structures are increasingly dissimilar (e.g., PM2 MCP P2 versus HK97 MCP), the argument of the logarithm approaches 0 as the evolutionary distance increases towards infinity. Please note the negative sign in the definition of D in (a) that inverts the $-\infty$ to ∞ .

The Fold of Some Viral Envelope Glycoproteins Recapitulates That of Cellular Proteins

Different scenarios have been postulated for the origin of viruses: (1) the "virus early" hypothesis which posits that viruses emerged from a pool of replicative elements that preceded the first protocell; (2) the 'regression' hypothesis which posits that viruses emerged from the degeneration of cells; (3) the "escaped genes" hypothesis which suggests that viruses are derived from cellular genes that acquired the capabilities required for the parasitic viral lifestyle; and (4) the "chimeric" hypothesis which proposes that viruses arose from replicative elements that existed prior to the first protocell and which later acquired virion structural elements from primitive cells (Krupovic and Koonin, 2017 in Further Reading). All four scenarios inescapably involved an initial exchange of genetic material with a (proto)cell, with further exchanges during the subsequent evolutionary steps.

Establishing virus relationships requires one to distinguish viral genes that are transferred vertically at infection from those exchanged horizontally with the host. Identification of structural homologs by comparison of 3D structures of cellular and viral proteins may help to identify those that have been exchanged between them. For instance, consider the three known classes of viral fusion glycoproteins (class I, II, III). All three classes mediate fusion with a cell membrane. Class II fusion glycoproteins are found in some viruses, including members of the *Togaviridae* and *Flaviviridae*. These viral class II fusogens are structural homologs of cell-cell fusogens such as epithelial fusion failure 1 (EFF-1) that is responsible for syncytia formation during *C. elegans* embryogenesis and gamete fusogen HAPLESS 2 (HAP2). Although viral and cellular fusogens share the same domain architecture (with three domains: DI, DII, DIII) and protein fold, their mode of action has been specifically adapted to the different tasks at hand. Fusion in the case of the viruses is unidirectional (heterotypic), while for cellular proteins fusion is bidirectional (homotypic) (Fig. 6).

These glycoproteins evidence the co-evolution of virus and host, but this co-evolution leaves us with the question as to the origin of these glycoproteins. Although the original directionality of the transfer might never be established, the broad distribution of HAP2 in cellular organisms, including some basal lineages, in contrast to the rather narrow distribution in viruses suggests that these viruses had recruited the corresponding cellular genes. In summary, this example adds further evidence that viral evolution cannot only conserve a useful fold, whatever its origin, but also fine tune it further to better serve viral purposes.

Fig. 6 Structural and functional conservation of viral and cellular proteins involved in membrane fusion. Side-by-side comparison of viral and cellular membrane fusogens in the post-fusion state. These cartoons represent the overall protein shapes and the arrangement and architecture of their domains, color-coded according to the classical color scheme originally given to the envelope protein of Tick-borne encephalitis virus (TBEV) E protein (PDB ID 1URZ) on the left. At the top left, the icosahedral enveloped TBEV virion (member of the *Flaviviridae* family) in a pre-fusion state (EMDB EMD-3752) (not to scale). At the center cellular protein EFF1 (PDB ID 4OJE), and on the right, HAP2 (PDB ID 5MF1). Each of the three proteins forms a trimer in the post-fusion state. Their corresponding partnering molecules are depicted in transparent white.

Would comparison of these viral fusion glycoproteins with one another be a useful tool to probe the ancient evolutionary relationships among the enveloped viruses? These glycoproteins in the viral envelope bind to the cellular receptor and facilitate membrane fusion with the host cell membrane. Host receptors evolve rapidly under pressure to escape viral infection. In response, viral fusogens are likely to also evolve more rapidly and thus to have only limited value as a signature indicating an ancient common ancestry. By contrast, evolutionary change to components such as the nucleoprotein might be more constrained because, in this instance, the protein being studied must interact with the viral genome. Although far from being agreed upon, currently there is an inclination to consider the nucleoprotein fold as a more informative character for the establishment of phylogeny for the enveloped viruses. This nucleoprotein is intimately associated with the genome which it enfolds, condenses, and encapsidates. However caution should be exercised when extrapolating a common ancestry for any two viruses based solely on the structural homologies detected for any single protein. One confounding factor is that many extant capsid protein and nucleoprotein folds appear to have originated from diverse cellular antecedents on independent occasions. These folds became “self” characters of a viral lineage when architecture, fold, and coupled functions were vertically transmitted together to viral descendants. For the above reasons, establishment of a valid structure-based viral phylogeny for the enveloped viruses awaits structure determination for many more enveloped virus proteins, including glycoproteins and nucleoproteins among others. Nevertheless, the correspondence between the folds of viral and cellular fusion glycoproteins reiterates that comparison of protein 3D structures is a powerful means to detect protein homology even when the sequence similarity has been lost.

Architectural and Functional Similarities With Cellular Structures: Are Exosomes Reminiscent of Enveloped Viruses?

Overall shape, domain architecture and fold are defining spatial properties not only of proteins but also of the structures of which they are a part. The assembly mechanism of a virion from its constituent biological components (e.g., nucleic acids, proteins, lipids) and the mechanical properties of the resultant virion rely on the specific 3D structures and physicochemical properties of its building blocks. These virus-specific assembly mechanisms, however, evolved in symbiotic relationship with the mechanisms active in the cellular host. This raises the question whether similar assembly processes are used by cellular organisms.

This brings us to exosomes, relatively small vesicles released by cells that carry different sets of proteins, nucleic acids, and lipids depending on the cell type of origin (Fig. 7(a) left). One type of exosome characterized early by cryo-EM was derived from rat liver. These were spherical structures that ranged from ~35 to ~80 nm in diameter (Fig. 7(b)). Subsequent analyses have visualized exosomes derived from other cell types. All so far share the same architecture including a lipid bilayer (composed mainly of cholesterol, ceramide, and glycerophospholipids) fenestrated by cellular membrane proteins (including integrins and tetraspanins, among others). Orientation of these membrane proteins relative to the lipid membrane is not always clear. Some exosomes have also been shown to

Fig. 7 Architectural similarities between exosomes and enveloped viruses. **(a)** Left, schematic of an exosome showing the vesicle (gray) harboring varied proteins (various shapes, differently colored). The orientation of the membrane proteins relative to the bilayer is not known. Right, schematic of a spherical, enveloped virus with membrane-bound glycoproteins (yellow and red). Their position on the envelope shown here is arbitrary. **(b)** 2D cryo-EM images of exosomes isolated from (above) supernatant of a human hepatic adenocarcinoma cell line (SK-HEP-1) and (below) from supernatant of a murine liver progenitor cell line (MP29); scale bar = 100 nm. incorporate viral proteins, for example during infection and transmission of hepatitis C virus (HCV), as well as during heterologous overexpression of HCV polyproteins (*unpublished results*). Others participate in the regulation of various pathophysiological processes including angiogenesis, inflammation, and metastasis. Fundamentally, exosomes function in intercellular communication and intercellular transport of biological material, including viruses such as hepatitis A, HIV, and poliovirus, within and between tissues. Their specific protein composition reflects the cell type from which they were purified and its pathophysiological state. Active research is currently ongoing to explore their potential use as biomarkers for human diseases and to investigate possible specificity of cargo or a pre-established ratio of structural components.

Exosomes originate from endosomal compartments, specifically from the multivesicular bodies (MVBs) that contain membrane-bound intraluminal vesicles. These (proteo-)vesicles assemble by budding into the lumen of the MVBs and can be released into the extracellular space via fusion with the plasma membrane. Architecturally exosomes are reminiscent of enveloped viruses (Fig. 7(a) right and 7(c)). Their morphogenesis is suggestive of pleomorphic members of the *Flaviviridae* family (e.g., hepatitis C virus, bovine viral diarrhea virus) rather than those of the *Alphaviridae* family whose biogenesis resembles the pinching-off of vesicles from the plasma membrane. However, both the vesicles formed as intraluminal vesicles and released via exocytosis (termed delayed exosome biogenesis) and those released by budding at the plasma membrane (termed immediate exosome biogenesis) can be defined as “exosomes”. The resemblance of the architecture and release mechanism between the budding exosomes and members of the *Retroviridae* family appears even stronger now than when originally postulated in 2003 in “The Trojan exosome hypothesis” by Gould and co-workers. They hypothesized not only that retroviruses use the pre-existing exosome biogenesis pathway for their assembly, but also that they take advantage of the pre-existing exosome uptake pathway for infection.

Exosomes – as we understand them today – appear to be byproducts of fundamental cellular physiology and housekeeping, and as such lack the specificity and the replicative character of viruses. Nevertheless, due to their architecture and their inherent self-assembly capability, exosomes might represent a suitable framework for the subsequent incorporation of specialized functions over evolutionary time. Interestingly, two of the simplest enveloped viruses structurally described so far, *Halorubrum pleomorphic virus* 2 (HRPV-2) and 6 (HRPV-6), strongly resembles a vesicle (Fig. 7(d)). Both are ssDNA viruses whose replication mechanism is not yet clear and they infect halophilic archaeal organisms (Archaea have also been shown to secrete exosomes). Their corresponding virions possess protruding spikes composed solely of a monomeric membrane-associated protein, VP5, whose fold has not been observed in any of the known viral class I-III fusogens.

Thus, can we consider certain enveloped viruses as being evolutionarily adapted exosomes? Might the evolution of the structure/architecture of the exosome in this direction have been steered by the relative abundance of a specific protein or protein class? A general or conclusive answer is not possible. Any claimed similarities between exosomes and viruses have always to be questioned. More convincing than current structural similarities may be the evident commonalities between retroviral and exosome biogenesis and release. In addition, the architectural mold offered by exosomes morphogenesis lend them exquisitely well as natural benchtops for experimenting how different 3D structures of cellular proteins associated to the envelope might modulate exosomes assembly and oversee recruitment of the internal cargo. Thus, while exosomes are extremely heterogeneous in size, in both their protein and nucleic acid compositions and tuneable by the cellular physio-pathological conditions, they engrave the archetypical composite architecture whose further evolution steered by the origination or enrichment of certain protein folds and motifs, might have led to the appearance of enveloped viruses.

These primordial and likely pleomorphic enveloped viruses may have been enriched for envelope-binding proteins and also for proteins with increased self-interactions. These same proteins might have come to form a proteinaceous shell (capsid) that could both protect the cargo engulfed by the vesicle and define the size of the resultant particles.

In subsequent steps, the incorporation of proteins with specialized capabilities, such as coating of an exterior membrane, self-assembly, and interaction with the host, might have rendered the vesicle membrane dispensable, thus giving rise to non-enveloped viruses (Fig. 7(d)). Today icosahedral capsid architecture is common in virions of diverse but discrete sizes, either enveloped or not. This development would reflect the selection of only those combinations of these viral coating proteins able to generate viable viral particles, thus leading to a discretization of the size of icosahedral virions. This discretization is currently described by the so-called triangulation number T , an integer number of defined values which increases with increasing virion size and which, for dsDNA viruses for example, broadly echoes the larger size of the viral genome packaged within.

Conclusions

During recent years, huge efforts have been made toward a comprehensive ordering of the viral universe through the use of sequence-based, and increasingly, structure-based methodologies. Nevertheless, deciphering viral phylogenies remains daunting. The vast diversity of viruses populating the biosphere remains mostly uncharacterized. More viral protein and virion structures, in particular, are needed! By their example, our few successes so far in using structural comparisons to establish viral evolutionary relationships portend the significant impact that this information can have across multiple scientific disciplines. Moreover, combined with elucidation of the modes of virion assembly and packaging, structural analyses may even provide a window on the earliest steps in viral evolution.

Acknowledgments

I am indebted to Prof. Dennis Bamford for bringing to my attention gaps in my knowledge – many of which still exist – and for the insightful comments on the manuscript. I am also grateful to Prof. David I Stuart for allowing me to use his original sketch of Fig. 5(a) and introducing me to the viral structure-based phylogeny field. I wish to thank also the past and present members of the Abrescia Lab for continuous support and discussions and in particular Ane Martinez-Castillo for carefully reading and commenting upon the manuscript.

Virus Classification Methods, the Increase Use of Sequences for Virus Classification

Viruses are the most abundant and genetically diverse acellular biological entities on the Earth. There are at least 10^{31} virus particles spread across most environments of the world, including marine and freshwater habitats and gastrointestinal tracts of metazoan, where the number of detectable viral particles exceeds 10–100 times that of cells. Viruses not only are large in number, but also have very important functions. Marine viruses, for example, play significant roles in inducing microbial mortality, shaping microbial community structure, and mediating the horizontal gene transfer between different host cells. There still exists an extraordinary amount of uncharacterized viral “dark matter” in the world. Therefore, studying and classifying these unknown viruses will help us make better use of virus resources and will lead to a better understanding of the ecology, history, and impact of the global viromes.

Virus classification is the process of naming and placing viruses accurately into a taxonomic system. This taxonomic system places viruses that are similar to each other in a hierarchy of relationships, and can describe viral diversity and the genetic and evolutionary relationships between different viruses, helping us understand the world of viruses. For international norms on virus classification, the formal taxonomic classification of viruses is the responsibility of the International Committee on Taxonomy of Viruses (ICTV) system which began to devise and implement virus naming and classification rules as early as the 1970s. The current classification of viruses is primarily based on biologically meaningful criteria, which divide the viruses into orders, families, subfamilies, genera and species.

Virus classification is an extremely difficult task for many families. Traditionally, virus classification relied on properties such as virion morphology, genome organization, replication mechanism, serology, natural host range, mode of transmission, and pathogenicity. Yet viruses sharing the above properties can reveal tremendous differences at the genome level. For example, classification of many phages used to be based on the presence, structure, and length of a tail, and this approach has been shown not to correlate with genomic information, leading to a very difficult situation and hundreds of mis-classified phages.

With the continuous development of technology, high-throughput sequencing and metagenomics have fundamentally changed virology. The number of viral genome sequences in the public databases is increasing rapidly, and these sequences are playing a significant role in virus classification. The most commonly used sequence comparison methods include multiple sequence alignment and phylogenetic analysis. In recent years, many molecular classification methods have been developed, and one that has drawn more and more attention from virologists is pairwise sequence comparison (PASC). In this article, we briefly describe various sequence comparison methods, introduce the PASC tool, and compare it with other methods.

Sequence Comparison Methods

Most sequence comparison algorithms can be broadly categorized by the scope of their application on sequences (local vs. global), by the number of sequences involved (pairwise vs. multiple), and by the involvement of sequence or sub-sequence alignment. In bioinformatics, sequence alignment is an approach to arrange sequences of DNA, RNA, or protein. Alignment of biological sequences helps to identify regions of similarity that may be a consequence of functional, structural, and evolutionary relationships between the sequences. The growing number of sequence data demands more efficient and faster alignment algorithms. A variety of algorithms and programs are available to suit a wide range of problems requiring sequence alignments as parts of their solutions. Depending on the specifics of a problem, different types of algorithms and their combinations may be the optimal choice.

Each pairwise alignment can be viewed as an array of per-residue operations transforming one sequence to the other. These operations are substitutions (called matches and mismatches in nucleotide alignments), insertions and deletions. In pairwise sequence alignment methods, scientists focus on finding the best-matching piecewise alignments of two query sequences by comparing the two DNA or protein sequences and finding the largest similarity matches between them. By inserting gaps, the two sequences with the same or similar residues are aligned up and down, and the number of matching residues is statistically analyzed to get a similarity score, which serves as a basis for determining the relationship between the two sequences. A generalization of this concept to multiple alignments is possible. Given a set of sequences, an alignment is called optimal if it has the maximal score over all possible alignments. Optimal alignments are not necessarily unique, two or more alignments can be tied with the same score.

Local alignments are useful for dissimilar sequences that are suspected to contain regions of similarity between arbitrary parts of sequences within their larger sequence context. There are many applications involving local alignment, including the search for orthologous genes or conserved protein domains. The alignment generated using local algorithms is easy to analyze mathematically,

which allows the construction of tools to access the statistical significance of the alignment. The Smith–Waterman algorithm is a general local alignment method based on the dynamic programming scheme but with additional choices to start and end at any place. This algorithm runs in a time proportional to the product of the lengths of sequences. Since this is too slow for large-scale searches, many heuristics have been developed that allow typical queries to be matched to gigabase-sized sequence archives in seconds.

BLAST is one of the most widely used bioinformatics programs for sequence searching. The heuristic algorithm it uses is much faster than other approaches, such as calculating an optimal alignment. However, algorithms like BLAST are not suitable for all applications. Although they are capable of picking up segments of high similarity, fragments may be inconsistently placed in the resulting alignment, and some fragments may belong to more than one individual alignment. Additional post-processing steps are usually required to generate consistent sets of local alignments, which makes the use of local alignment complex in applications involving uniform computing of identities.

Global sequence alignment attempts to match as many characters as possible, from beginning to the end of both the sequences to find the best possible alignment. The Needleman-Wunsch algorithm is a general global alignment technique, which is based on the dynamic programming. Global alignment is mainly used to find closely related sequences and its running time is the same as that of the local alignment. Additionally, hybrid methods, known as semi-global, search for the best possible partial alignment of the two sequences. This is especially useful when the downstream part of one sequence overlaps with the upstream part of the other sequence. Another case where semi-global alignment is useful is when one sequence is short and the other is very long. In this case, the short sequence should be aligned globally but only a local alignment is required for the long sequence.

Multiple sequence alignment is an extension of pairwise alignment to incorporate more than two sequences at a time. However, they are often used for different purposes, such as detecting weak or scattered similarities on a set of sequences known to share a common structure or function. And thus, multiple sequence alignment is the basis for evolution analysis, consensus generation and structure prediction. Computing an optimal multiple sequence alignment is a computationally costly task, and most implementations use various heuristics to approximate the alignment in a reasonable time. So there is no available optimal solution for multiple sequence alignment and all methods are heuristics, such as progressive/hierarchical alignment, and iterative alignment. There are many multiple sequence alignment tools available: Clustal Omega, Clustal W, MAFFT, MUSCLE, T-Coffee, ProbCons, ProDA, MSAProbs, GLProbs, and so on.

Phylogenetic analysis is also a popular method for the comparison of more than two sequences. A phylogeny or evolutionary tree is a mathematical structure which is used to model the historical relationships between groups of organisms or sequences. The types of methods used to construct phylogenetic trees include distance-based methods (such as neighbor-joining), parsimony, maximum likelihood, and other probabilistic inference techniques. The most common distance-based methods utilize multiple sequence alignments to estimate the evolutionary distance between each pair of sequences and reconstruct the tree from the distances. Either protein sequences or DNA sequences can be used. Phylogenetic analysis was used to support the classification within the vast majority of virus families described in the ICTV Report on Virus Taxonomy. Nearly all methods of phylogenetic analysis share a number of fundamental assumptions, including that the sequences in the multiple sequence alignment are homologs. So it can also be used to the classification of a large group of distantly related viruses. For example, phages consist of many different families. Therefore, the conventional phylogenetic analysis that uses genomic sequences or individual protein sequences would not work for the classification of phages as a whole group. A ‘phage proteomic tree’ was developed to classify phages by the overall similarities of all protein sequences present in the phage genomes.

Alignment-free approaches to sequence comparison can be defined as any method of quantifying sequence similarity/dissimilarity that does not use or produce alignment (assignment of residue-residue correspondence) at any step of algorithm application. The alignment-free approaches are mathematically well founded in the fields of linear algebra, information theory, and statistical mechanics, and calculate pairwise measures of dissimilarity or distance between sequences. The rationale behind this method is that similar sequences share similar words/k-mers (subsequences of length k) and mathematical analysis of the k-mers’ occurrences can give a good relative measure of dissimilarity. For example, for two virus genome sequence, collect the common k-mers, calculate an array of numbers (by counting the number of times each particular k-mer appears within the sequences) and use this to quantify the dissimilarity between sequences. Conveniently, most of these measures can be directly used as an input into standard tree-building software, such as Phylip or MEGA.

Although phylogenetic analysis is well established as a tool for virus classification, it is usually computationally intensive and requires expertise to perform the analysis and interpret the results. For the alignment-free method, it will need more memory as the k-mer length increases. Furthermore, there are still many problems that need to be solved although the method has been applied in a few programs.

Sequence-Based Virus Classification Methods Review

With the advances in sequencing technologies, viral genome sequences in public databases are increasing rapidly. Many of these sequences are from metagenomics sequencing, and there is a lack of other information about the viruses associated with them. The traditional virus classification method, therefore cannot be applied to them. As a result, virus classification methods based on viral genome sequences have become popular and indeed essential, in recent years. Virus classification methods solely based on viral genome sequences have been accepted by the international community because they usually produce very similar results to those obtained by the traditional methods.

DEmARC

DEmARC (DivErsity pArtitioning by hieRarchical Clustering) is a quantitative, genetics-based framework for classification of a virus family. This approach performs a multiple alignment of conserved proteins within a virus family, and estimates the pairwise evolutionary distances (PEDs) by maximum likelihood inference. The distribution of PEDs is used to quantify genetic divergence and classify viruses at hierarchical levels in the family. DEmARC has been applied to the classification in the families *Picornaviridae*, *Filoviridae*, and *Mesoniviridae*. However, because DEmARC requires the manual selection of protein sequences and optimization of the results of multi-sequence comparison, it is not well suited for high-throughput applications.

Natural Vector

The Natural Vector method is an alignment-free tool to characterize and analyze virus sequences and classify viral genome sequences. This approach constructs a one-to-one correspondence between genome sequences based on a 12-dimensional genome space. The vector contains the quantities of each of the four bases, their mean positions in the sequence and the normalized variances of the position of each. The distance between two genome sequences is defined as the distance between their natural vectors. This recasts a variable length nucleic acid sequence as a fixed-length low dimensional vector and has been expanded to various similar methods such as 60-dimensional protein space and an 18-dimensional natural vector which also considered covariance between nucleotides. This method provides a very fast way to characterize phylogenetic relationships amongst viruses.

SDT

The Sequence Demarcation Tool (SDT) is a stand-alone program with graphical interface that allows classification of virus sequences based on sequence pairwise identity (a robust Needleman-Wunsch pairwise-alignment). It takes DNA or protein sequences as input and aligns each unique pair of sequences, calculates pairwise similarity scores, and displays a color-coding matrix for those scores. It also generates the corresponding plot and a text file containing the results of the analysis. SDT has been recently used for the reclassification of viruses in the family *Geminiviridae*, in the classification of viruses in the families *Circoviridae*, *Nanoviridae*, *Amalgaviridae*, *Smacoviridae*, and *Alphasatellitidae*. The virus sequences can be classified in batches if computational power is limited.

GRAViTy

Genome Relationships Applied to Virus Taxonomy (GRAViTy) is a stable algorithm that classifies viruses based only on sequences. GRAViTy first uses the known viral proteins and genome sequences to establish the Protein Profile Hidden Markov Model (PPHMM) and Genomic Organization Model (GOM) databases. Then, by calculating the distance between the PPHMM and GOM signatures of two virus sequences, the evolutionary distance between the two viruses can be inferred, and used for virus sequence classification. This approach can be effectively applied to the family-level classification of eukaryotic viruses.

ViPTree

ViPTree is a web-based classification tool to generate viral proteomic trees for the classification of viruses based on genome-wide similarities. Specifically, the proteomic tree is generated by BIONJ based on a genomic distance matrix computed from the normalized tBLASTx scores. Users can upload viral genomic sequences from genomics or metagenomics studies and generate proteomic trees using their own sequences and selecting reference viral genomes from the GenomeNet/Virus-Host database. For the uploaded viral genomes, ViPTree also provides visualization of comparative genomes and automatically annotates gene functions. In addition, they also developed a command line tool, ViPTreeGen, for viral proteomic tree generation.

ViCTree

ViCTree is a bioinformatics framework which can automatically synchronize with viral sequences in the National Center for Biotechnology Information (NCBI) GenBank and generates an interactive maximum-likelihood phylogenetic tree combined with distance data. Specifically, all known viral protein sequences available in GenBank are downloaded and compared with a curated set of seed protein sequences by BLAST. Significant matches are clustered by using CD-HIT with a user-specified identity threshold parameter, followed by multiple sequence alignment and RAxML maximum likelihood tree generation. ViCTree is capable of automatically building new phylogenies when novel viral species data are available in public databases. The built-in ViCTreeView visualization tool enables users to visualize and explore distances in the context of the tree in a web browser. This approach is currently set up for the *Herpesviridae*, *Parvoviridae*, and *Densoviridae* families but is flexible and can be adapted for any other virus family.

PASC Description and Application

PASC, one of the most widely used sequence-based tools for virus classification, was developed by NCBI. PASC provides a web interface ("See Relevant Websites section"), which makes it easy to navigate and perform analyses. For a given virus family/group, complete genome sequences are retrieved from the NCBI viral genomes collection, which includes both reference sequences and genome sequences of other members of the same species. These sequences, together with their NCBI taxonomy lineages, are stored in a database. The tool's database now stores pairwise identities for complete genomes/segments of 66 virus families/groups. Data in the system are updated daily to reflect changes in virus taxonomy and additions of new virus sequences to the public database.

The latest version of PASC uses a process of automated BLAST alignment to identify regions with significant sequence similarity. To be specific, two rounds of BLAST are performed on each pair of genome sequences. In the first round, the protein sequences of one genome, translated in six reading frames, are searched against the other genome using tblastn. The amino acid alignments in the tblastn results are converted back to nucleotide alignments. In the second BLAST round, pairwise blastn is carried out on the nucleotide sequences of the genomes. And then, a consistent set of hits are selected from the two sets of BLAST results, giving preference to higher identity hits and trimming overlaps out of lower identity hits, to generate a set of hits that do not overlap in any region on any genome. Pairwise identities are calculated as the total number of identical bases in local hits divided by the average length of the genome pair. Furthermore, the number of virus pairs at each percentage is plotted. A chart is plotted showing the distribution of identities between all members of the selected virus family or group, and can help determine the demarcations at strains, species, genera, and subfamilies level. If the two genomes belong to the same species according to their assignment in the NCBI taxonomic database, the pair is represented in green; if the two genomes belong to different species but belong to the same genus, it is yellow; and if they belong to different genera, it is peachy. Both linear and log scales are available for the y-axis (number of pairs). The gap sizes between the peaks indicate the possibility that these regions will be filled with sequences from novel viruses. The larger the gaps, the more likely that they are the true threshold to separate species/genera. When given a novel virus, PASC will begin to compute the alignments, or to extract them from the database if the query is a member of the group. At the end of the process, a user is presented with a list of closest matches. Matches can be selected to visualize their positions on the identity distribution chart. A new virus sequence can be tested with this system within a few minutes to suggest the taxonomic position of the virus in these families.

PASC has been successfully applied to many viral families. First, frequency distributions of pairwise genetic identity scores generated by PASC can be used to manually identify taxonomically optimal species or genus demarcation thresholds.

The mononegaviral family *Filoviridae* has eight members assigned to three genera and seven species. Previously, arbitrarily chosen filovirus genome sequence divergence values ($\approx 50\%$ for genera, $\approx 30\%$ for species) and phenotypic virus or virion characteristics were used to decide genus and species demarcation. After comparison of 152 distinct near-complete, coding-complete or complete filovirus genome sequences using PASC, optimal genus demarcation at the 55%–58% sequence diversity threshold range for genera and at the 23%–36% sequence diversity threshold range for species were revealed (Fig. 1). These thresholds do not change the current official filovirus classification, so they were implemented as filovirus taxon demarcation criteria that may solely be used for filovirus classification in case additional data are absent. In addition, PASC can be applied to multi-segmented viruses. For example, the mammalian arenavirus genome consists of two single-stranded ambisense RNA molecules. The two RNA segments are designated Small (S) and Large (L). PASC of arenavirus genomes and NP amino acid pairwise distances support the modification of the present classification. For the S segment, the pairwise nucleotide sequence

Fig. 1 Screenshot of PASC result in log scale after comparing filovirus genome sequences.

identities within the same proposed genus are higher than 40%, while those from different proposed genera are lower than 29%. PASC analysis indicates that an ideal genus separation cutoff range of 29%–40% sequence divergence for the S segment, and 30%–35% for the L segment. In order to introduce the fewest changes and minimal inconsistency with the current arenavirus classification scheme, nucleotide sequence identity > 80% in the S segment and > 76% identity in the L segment were chosen as values for viruses that should belong to the same species.

Newly sequenced viruses can be placed into the correct taxonomy group using PASC. Given a novel virus genome sequence, PASC compares it to a defined set of publicly available sequences and gives a list of matches within the family from the highest to the lowest based on BLAST identity. According to top pairwise identities and species or genus demarcation thresholds revealed by PASC, users can easily assign a novel sequence to the most appropriate genus, species or other taxonomic unit. Dot matrix and text views of pairwise alignment between genome sequences can also be accessed. Lymphocystis disease, which is provoked by the iridovirus lymphocystis disease virus (LCDV), affects marine and freshwater fish species worldwide. Direct sequencing of the virome of lymphocystis lesions from affected *S. aurata* fish was used to obtain the complete genome of a new LCDV-Sa species (GenBank accession number KX643370) that is the largest vertebrate iridovirus sequenced to date. Pairwise identities were calculated using PASC and it was found that LCDV-Sa shared only 54.67% identity with LCDV-C (NC_005902.1) and 38.95% identity with LCDV-1 (NC_001824.1) while LCDV-1 and LCDV-C shared 41.53% identity with each other. Accepted viral species within other genera of the *Iridoviridae* family show identity values above 85%. Therefore, LCDV-Sa represents a novel species of the genus *Lymphocystivirus*. Additionally, users can find novel genera with the help of PASC. Pteromalus puparum negative-strand RNA virus 1 (PpNSRV-1) is a novel negative-stranded RNA virus from a parasitoid wasp. It mediates the offspring sex ratio by decreasing female offspring numbers. PASC analysis of the PpNSRV-1 genome (Genbank accession number KX431032), reveals 13.8% identity to Soybean cyst nematode virus 1 (SbCNV-1; nyamiviral genus Socyvirus; GenBank accession number NC_024702), 12.1% to Midway virus (MIDWV; nyamiviral genus Nyavirus; GenBank accession number NC_012702), 12.3% to Nyamanini virus (NYMV; nyamiviral genus Nyavirus; GenBank accession number NC_012703), and 10.9% to Sierra Nevada virus (SNVV; nyamiviral genus Nyavirus; GenBank accession number NC_024376), with those viruses being the closest known relatives of PpNSRV-1. The 13.8% identity of the closest relative is below the 17% identity between nyavirus and socyvirus genomes, showing the need for a novel nyamiviral genus. The ICTV Nyamiviridae Study Group has agreed with the assessment.

Finally, PASC can also perform simulation of taxonomy changes. In other words, it allows users to test ideas for genus/species demarcation and see what taxonomy changes are needed using existing sequences to achieve user-selected demarcations. Even though NCBI uses the official ICTV taxonomy names whenever possible, there are times when GenBank sequences are assigned to incorrect virus names by submitters, which will lead to a mixture of colors in the peaks. For example, green or yellow bars are mixed with the dominating peach bars. To explore different demarcations, users can try different numbers for “Merge species above” and “Separate species below”, and for “Merge genera above” and “Separate genera below” as indicated at the lower left section of “Taxonomy changes:”, see for instance Fig. 2. In addition, PASC also lists recommended taxonomy changes needed for such a result, some of which are shown at the bottom of the webpage. Another taxonomy change simulation tool in PASC splits genomes into subgroups, which called “Split genomes below” (at the lower left of Fig. 2). After this is applied, users can see how genome groups are formed.

Advantages of PASC Compared to Other Methods

In recent years, many methods and tools have been applied to the classification of viruses (Table 1). Since for many viruses only sequence information is available, the tools and methods developed now aim to achieve rapid sequence-based classification and identification. These tools fall into three major categories: phylogenetic analyses such as ViCTree and ViPTree; alignment-based such as PASC and SDT; and alignment-free such as NVR and GRAVITY. PASC, one of the first such methods, was brought online in 2008. Its core classification algorithm and visualization method were updated in 2014.

Unlike classification methods based on the phenotypic properties of viruses, PASC is a quantitative tool. For those virus families that are suitable for PASC analysis, demarcations can be easily determined and new viruses can be clearly placed into the correct taxonomy. However, there are times when PASC alone cannot give a definite classification, and other viral properties have to be considered.

The most commonly used sequence-based virus classification tool is phylogenetic analysis. Compared to this approach, PASC is less computationally intensive and can be easily updated with new sequence data. In addition, PASC results are relatively easy to interpret, and this could be done potentially by a computer program without human intervention. It would therefore be possible to set up an automatic system for high throughput classification.

PASC was greatly improved by using the BLAST-based alignment method. Previously, PASC used a pairwise global alignment algorithm to calculate viral genome similarity. Although this method was applicable to some virus families/groups, such as papillomaviruses and *potyviruses*, the results were not very good for others. Circular genome sequences are deposited with inconsistent starting and ending coordinates, which will cause trouble for the global alignment approach. The BLAST-based alignment (combination of blastn and tblastn) method selects the better of the two alignments for the same region in the genomes, which effectively applies the most appropriate blast program automatically for protein coding and non-coding regions. This approach can find all possible regions of similarity in the genome and improved the results for almost all viral families/groups.

The PASC tool is one of NCBI's web tools synchronized with NCBI's viral genome collection and taxonomy database that are updated regularly. It runs very fast, and results can usually be obtained within minutes. The tool is online, so there is no software

Fig. 2 Frequency distribution of pairwise identities from the complete genome sequence comparison of 737 viruses in Rhabdoviridae, and the simulation of taxonomy changes using proposed species and genus demarcations. A good taxonomy can be achieved when 75% is used as the species demarcation. Black arrowheads on the x-axis of the upper and lower plots show the difference after doing simulation of taxonomy changes.

to download/install, no parameters to set, and everybody uses the same algorithm and same dataset, so that the results are directly comparable. PASC is one of the more important sequence-based alignment virus classification tools and provides support to the ICTV study groups for the families of *Polyomaviridae*, *Arenaviridae*, *Bornaviridae*, *Arteriviridae*, and *Filoviridae*.

Limitations of PASC

Although PASC has been updated in 2014 and applied successfully to more virus families, the approach has some limitations.

First of all, PASC is not suitable for virus families whose current classification is largely based on virus morphologies, such as phages in the families of *Siphoviridae* and *Podoviridae*.

Second, although demarcation values were established in PASC for several virus families, for most virus families no cutoff values in sequence identity percentages are currently suggested to separate species and genera. The separation points between

Fig. 3 Limitations of PASC in virus families with highly diverse sequences. PASC results in the *Pestivirus* genus (a), the *Hepacivirus* genus (b), and the *Flaviviridae* family (c).

different classification levels need to be manually selected, which would result in the decrease of efficiency and accuracy. When the distribution suggests that one cutoff could be selected as demarcation in PASC, other criteria (e.g., host) should be considered to select the suitable one.

Furthermore, the use of the whole genome in PASC may not work well for virus families with highly diverse sequences. One assumption of PASC is that the taxonomic thresholds of genera and species are the same among different evolutionary lineages of a family. Thus, if the threshold (BLAST score) for species assignment in one genus is 85, then it would also be the threshold for other genera in the same family. However, in many virus families, uniform threshold definitions cannot be applied. For example, the *Pestivirus* genus of the virus family *Flaviviridae* shows mean species threshold of 74 (range 72–76) between nucleotide sequences of the genomes (Fig. 3(a)). In contrast for the *Hepacivirus* genus, it is 51 (range 48–53) (Fig. 3(b)). When applied to the entire *Flaviviridae* family, PASC shows a broad range of pairwise distances, with no clear divide between inter- and intra-species pairwise distances (Fig. 3(c)).

Conclusion

The current standard method of viral classification has been challenged by the large amount of data generated by high throughput sequencing. There is an urgent need to develop novel approaches to classify viruses using their sequences only. Various sequence-based methods currently exist, amongst which PASC is frequently used due to its good performance and ease of use. PASC is an online tool, and there is no need for users to install any software/package, to download datasets or to set parameters. It therefore avoids the inconsistency of results between different users who choose different protocols to calculate the pairwise identities. In addition, it runs quickly and a new virus sequence can usually be tested within a few minutes to suggest optimal taxonomic position in selected family. The tool has already been successfully applied to a number of virus families and increasingly species/genus demarcation criteria revealed by PASC are being adopted by ICTV Study Groups. However, PASC, and all sequence-based virus classification methods, have shortcomings. For example, PASC may not work well for virus families with highly diverse sequences. Hence, further improvement or a combination of different algorithms need to be investigated in the future.

Computational Analysis of Recombination in Viral Nucleotide Sequences

Miguel Arenas, Department of Biochemistry, Genetics and Immunology, University of Vigo, Vigo, Spain and CINBIO (Biomedical Research Center), University of Vigo, Vigo, Spain

© 2021 Elsevier Ltd. All rights reserved.

Introduction

Genetic recombination consists of an exchange of genetic fragments that shuffles mutations to generate genetic variants upon which natural selection operates. Different types of recombination have been described (e.g., [Scheel et al., 2013](#)). Homologous recombination occurs in the same location in both parental strands and it is often observed in viruses (i.e., in movements of genetic material by horizontal gene transfer, HGT). By contrast, non-homologous recombination exchanges genetic fragments placed at different locations and can lead to aberrant genetic data ([Galli and Bukh, 2014](#)) but also it can be useful for virus populations, for example, providing new enzyme cleavage sites that increase virulence ([Godoy et al., 2014](#)). Some viruses (i.e., influenza) with segmented genomes can also exchange complete genome segments in a recombination-based reassortment process ([McDonald et al., 2016](#)).

Recombination occurs in a large variety of organisms, predominantly in bacteria and viruses ([Perez-Losada et al., 2015](#); [Simon-Loriere and Holmes, 2011](#)). Concerning the latter, the recombination rate broadly varies among known viruses ([Perez-Losada et al., 2015](#)). Recombination is particularly frequent in dsDNA viruses where it is involved in replication and DNA repair and, in some RNA viruses (especially in retroviruses such as HIV) where the recombination rate per nucleotide can surpass the mutation rate ([Jetzt et al. 2000](#)) it can purge deleterious variants and accelerate the emergence of advantageous variants.

Recombination has been associated with the expansion of viral populations, emergence of outbreaks and new viruses, increase of fitness in new environments, modification of transmission specificities, increase of virulence and pathogenesis, escape from the immune system and antiviral therapies, among others ([Perez-Losada et al., 2015](#); [Simon-Loriere and Holmes, 2011](#); [Arenas et al., 2016](#)). The evolutionary innovations required to acquire these achievements in viral populations would be slow or inaccessible by only the mutation process, thus favouring the establishment of genetic recombination. At the inter-host level, understanding recombination can produce epidemiologically-relevant circulating recombinant forms (CRFs) that may become stable over time ([Lihana et al., 2012](#)) (a list of common HIV-1 CRFs is referenced in the section Relevant Websites) and that can favor failure of vaccines against viruses such as the HIV ([Barouch et al., 2013](#)). At the intra-host level, recombination can increase viral diversity and shuffle resistance mutations, which overall increase the diversity of drug resistance genotypes, allowing viral adaptation to the immune system and antiviral therapies ([Charpentier et al., 2006](#)). In this concern, modeling recombination, together with the viral life cycle and viral fitness, could be useful to improve the design of antiviral therapies. However, models that accurately mimic Virus Evolution are still challenging due to the complexity of parameterizing these processes accounting for a temporal variation of the environment ([Gog et al., 2015](#)).

The relevance and impact of recombination in Virus Evolution is clear. Consequently, evolutionary biologists and molecular virologists require the analysis of recombination, at qualitative and quantitative levels, from genetic data. For this reason, a variety of computational methods have been developed and implemented in currently available frameworks, to analyze recombination from genetic sequences. The influence of recombination on phylogenetic tree inference and derived evolutionary analyses, including guidelines on how recombination should be considered to avoid estimation biases will also be described and illustrative case studies of viral genetic data that evolved with recombination presented.

Computational Estimation of Recombination

The large variety of consequences derived from recombination in viruses leads to the requirement of accurate analyses of recombination, including the estimation of recombination rates and recombination breakpoints. Currently, diverse methods (some of them implemented in computational frameworks) can be used to perform these analyses. These methods present differences concerning their performance ([Posada and Crandall, 2001](#)) and so selecting a particular method can be complex. The choice is usually based on the kind of analysis desired (i.e., detect presence/absence of recombination, map recombination breakpoints, quantify constant or heterogeneous recombination rate along the genetic sequences), genetic marker or available computational resources ([Martín et al., 2011](#)). An updated list of well-established computational frameworks to detect recombination breakpoints and estimate recombination rates from genetic sequences (together with their main features) is shown in [Table 1](#). It is recommended to explore the comprehensive list of recombination analysis frameworks provided by David Robertson's Lab (section Relevant Websites). In the following subsections the most used methods and frameworks to analyze recombination in genetic sequences will be summarized.

Rapid Tests to Detect the Presence of Recombination

The presence or absence of recombination can be evaluated with statistical tests ([Wiuf et al., 2001](#)) that are computationally rapid. In general, these tests provide accurate predictions in data with large genetic diversity and recombination ([Posada, 2002](#)) (particularities that are frequently observed in viruses) but there are exceptions. While tests based on homoplasy are more accurate

Table 1 Commonly used frameworks to estimate recombination rate and recombination breakpoints in a multiple alignment of genetic sequences. For each framework, the table indicates the underlining statistical approach (ML and ABC refer to maximum-likelihood and approximate Bayesian computation, respectively), type of genetic marker of the input dataset (SNP refers to single nucleotide polymorphism), estimation of homogeneous and/or heterogeneous recombination rate along the sequences, prediction of recombination breakpoints, operating systems where the framework can run and the corresponding references. In italic frameworks are highlighted that have been frequently used or that are recommended based on the author's experience. Additional software to analyze recombination is shown in a web page provided by David Robertson's Lab (section Relevant Websites)

analyzing data with low genetic diversity, other tests [like those based on the maximum chi-square and the tests implemented in the framework *RDP* (Martin *et al.*, 2015)], are more confident in data presenting high genetic diversity (Bruen *et al.*, 2006). An interesting test is the pairwise homoplasy index (PHI), implemented in the *PhiPack* software (Bruen *et al.*, 2006), because it can distinguish recurrent mutation from recombination. Because of the different performance of these recombination tests, it is recommended to use several tests and make conclusions from the overall findings (Posada, 2002). In this concern, well-established frameworks implementing multiple recombination tests are *RDP* and *PhiPack*.

Additionally, some recombination tests have been developed considering the bias that recombination can make on the phylogenetic tree reconstruction (Schierup and Hein, 2000a). In particular, a dataset of genetic sequences presenting recombination can be split into fragments that have evolved under different evolutionary histories (Box 1 and Fig. 1), showing a phylogenetic tree incongruence that can be statistically quantified. Phylogenetic incongruence tests (e.g., Strimmer and Rambaut 2002) have been developed using this peculiarity and can be considered as a complement of the previously presented recombination tests. A limitation of phylogenetic incongruence tests is that recombination does not always lead to phylogenetic incongruence [the recombinant fragments could share a most recent common ancestor (MRCA) and could present a similar evolutionary history], which can result in false negatives.

Identification of Recombination Breakpoints

Generally, recombination events are heterogeneously distributed along genomes. Certain regions of a genome (recombination hotspot regions) can present a high frequency of recombination respect to the neutral expectation while other regions (recombination coldspot regions) can display lack of recombination with respect to the neutral expectation (Smyth *et al.*, 2014). In this concern, the identification of recombination breakpoints has been used in viruses to map recombination hotspots (e.g., Dalmon *et al.*, 2017) but also to characterize recombination forms (e.g., Archer *et al.*, 2008), detect adaptive recombination (e.g., Arenas *et al.*, 2016; Monjane *et al.*, 2011), understand molecular mechanisms of recombination (Perez-Losada *et al.*, 2015) and perform evolutionary analyses accounting for recombination (Box 1).

Most of the methods to detect recombination breakpoints are based on the statistical quantification of a particular property (i.e., phylogenetic tree) that differs at both sides of the recombination breakpoint. Basically, these methods explore the genetic location (breakpoint) with the highest variation of the cited property along the sequences (Martin *et al.*, 2011). The searching for recombination breakpoints along the sequences was originally explored with sliding windows where the breakpoint is moved along the sequences and it is statistically evaluated at every location (e.g., Holmes *et al.*, 1999), but more recent methods optimized the procedure by considering a probabilistic/heuristic search along the sequences (e.g., Westesson and Holmes, 2009).

Box 1. The influence of recombination on phylogenetic tree reconstruction and inferences derived

The genetic segments involved in a recombination event could have evolved under different evolutionary processes and present different evolutionary histories as phylogenetic trees (Fig. 1). Therefore, a recombination event can result in two phylogenetic trees (one for each fragment), which may differ among them (phylogenetic incongruence). The combination of these phylogenetic trees produces a phylogenetic network that is traditionally called an ancestral recombination graph (ARG) (Fig. 1) (Arenas, 2013; Griffiths and Marjoram, 1997). Consequently, the reconstruction of a single phylogenetic tree from genetic sequences that suffered recombination can be biased resulting in a phylogenetic tree with an incorrect topology and branch lengths (Schierup and Hein, 2000a).

If the phylogenetic tree is biased, subsequent evolutionary analyses could also be biased. For example, the estimation of the nonsynonymous (dN) to synonymous (dS) substitution rates ratio (dN/dS), which is a well-established measure of selection in protein-coding sequences (Hurst, 2002) and that is frequently used to study Virus Evolution at the molecular level (e.g., Poon *et al.*, 2007; Arenas, 2015), can be biased if recombination is ignored. In particular, this bias consists of estimating false positively selected sites (PSS) (Arenas and Posada, 2014; Anisimova *et al.*, 2003). Another bias caused by recombination is related to the ancestral sequence reconstruction (ASR). Incorrect ancestral sequences of the internal nodes of a phylogenetic tree can be inferred in data that suffered recombination (Arenas and Posada, 2010b). The ASR error increases with the recombination rate and the genetic diversity (Arenas and Posada, 2010b). Other evolutionary analyses can also be affected by recombination. For example, ignored recombination can lead to a loss of the molecular clock, apparent homoplasies and false substitution rate heterogeneity (Schierup and Hein, 2000a,b; Arenas *et al.*, 2018). Altogether, if recombination is found [i.e., recombination breakpoints are detected and delimit recombinant fragments], one should perform the evolutionary analyses (i.e., dN/dS estimation or ASR) by one of the following procedures. (1) Separately analyze each recombinant fragment by using the phylogenetic tree inferred for the corresponding genetic fragment (e.g., Perez-Losada *et al.*, 2011; Perez-Losada *et al.*, 2009; Arenas and Posada, 2010b). (2) Apply an analytical method that performs the estimation accounting for recombination [i.e., for dN/dS see (Arenas *et al.*, 2015; Lopes *et al.*, 2014; Wilson and McVean, 2006) or for the reconstruction of a full phylogenetic history (i.e., recombination network) see (Huson, 1998)].

Several well-established frameworks to detect recombination breakpoints are presented in Table 1. RDP is one of the most used frameworks to perform this task probably because it implements a variety of algorithms and includes a graphical user interface (GUI). Another well-established framework is Hyphy (Pond *et al.*, 2005) [together with its online web server Datamonkey (Weaver *et al.*, 2018)] through the algorithm GARD (Pond *et al.*, 2006).

Estimation of Recombination Rates

The rate at which recombination events occur during the evolutionary history of a genetic dataset can also be estimated. Instead of estimating the recombination rate per generation per site (r), most methods estimate the population recombination rate $\rho = 2nNrL$, where $n = 1$ or 2 for haploid or diploid populations, respectively, N is the effective population size and L is the sequence length in nucleotides. Since ρ depends on N , it must be carefully interpreted (i.e., when comparing ρ estimated in two populations with different sizes or under variable population sizes) (e.g., Kuhner *et al.*, 2000). The estimation of the recombination rate, either at the molecular or population level, has been developed using different statistical approaches, including maximum likelihood (ML) (e.g., Kuhner, 2006), Bayesian (e.g., Kuhner, 2006; Wilson and McVean, 2006) and approximate Bayesian computation (ABC) (Lopes *et al.*, 2014), among others (Martin *et al.*, 2011). A variety of software implements the estimation of the recombination rate using these approaches (Table 1). Some well-established frameworks to perform this estimation are LDHAT (McVean *et al.*, 2004), Lamarc (Kuhner, 2006), RDP and OmegaMap (Wilson and McVean, 2006). The program LDHAT implements the coalescent composite likelihood method developed by Hudson (2001) into a Bayesian approach and can estimate variable recombination rate along sequences under different genetic markers. Another traditionally used framework is Lamarc, which implements ML and Bayesian approaches to estimate a population recombination rate that is assumed constant along the sequences. Lamarc can estimate additional evolutionary parameters such as the population growth rate and the migration rate, which can be useful to facilitate the understanding of the evolutionary process. However, both LDHAT and Lamarc can be problematic in reaching convergence between independent runs, especially with large datasets. The software RDP has been frequently updated, it is quite robust in reaching convergence between independent runs and includes a user-friendly GUI for Windows. Today it seems the most widely used framework to analyze recombination (more than 5000 citations from its four versions) and it has been widely used to analyze genetic data in diverse viruses (e.g., Faria *et al.*, 2017; Castelhanos *et al.*, 2017). Another very useful framework is OmegaMap. It is based on the product of approximating conditionals (PAC) likelihood and estimates recombination, dN/dS and substitution rates that can vary among user-specified partitions of protein-coding sequences. Finally, CodABC (Arenas *et al.*, 2015) is a framework developed by this author and others to accurately estimate recombination, substitution and dN/dS rates from protein-coding sequences and has already been applied to analyze a variety of HIV-1 datasets (Lopes *et al.*, 2014). It is based on ABC and its goal is derived from considering interactions between different evolutionary parameters (i.e., dN/dS is estimated accounting for recombination or the recombination rate is accurately estimated in data with low genetic diversity, outperforming other methods). On the other hand, ABC requires a large number of computer simulations [which are computationally intensive for coding data due to the large size of the codon exchangeability matrix (61×61 , excluding stop codons) (Arenas and Posada, 2012)] and this results in long computer times. Conveniently, CodABC can run in parallel on a multiprocessor machine allowing a reduction in computational time.

Fig. 1 Illustrative example of an ancestral recombination graph based on two recombination breakpoints. The figure shows an ancestral recombination graph (ARG) for a sample of 4 sequences (A, B, C, D) with 100 sites (i.e., nucleotides). Two recombination events (RE, dashed line) occurred with breakpoints at position 40 and 70, leading to three recombinant fragments 1–40, 41–70 and 71–100. Going backwards in time, a recombination event generates two lineages each (shown with different colors), for every recombinant fragment. Each recombinant fragment presents a specific phylogenetic tree (shown on the right) that can be built from the ARG by following the nodes and branches containing the corresponding fragment until reaching its most recent common ancestor (MRCA). The phylogenetic trees of the recombinant fragments can differ in topology, branch lengths and MRCA. The oldest MRCA is the root of the network and it is usually referred to as the grand most recent common ancestor (GMRCA).

Reconstruction of Phylogenetic Recombination Networks

The genetic regions on both sides of a recombination breakpoint can present different evolutionary histories (Box 1 and Fig. 1). Consequently, the inference of the evolutionary history of a genetic dataset that has undergone recombination should not be done by reconstructing a single phylogenetic tree (Mallo *et al.*, 2016). Instead, one should reconstruct a phylogenetic tree for each recombinant fragment or a phylogenetic network (the ARG) where each recombination event constitutes a reticulate node (Fig. 1). The ARG was originally simulated from the coalescent with recombination (Hudson and Kaplan 1988) and this modeling allowed its implementation in likelihood functions. However, calculating a likelihood function that considers recombination requires huge computational costs due to the large number of ARGs that should be explored, and thus leads to the use of methods (i.e., composite-likelihood models) to simplify the likelihood function (McVean *et al.*, 2002). The inference of the ARG has been implemented in several evolutionary frameworks. The software BEAST (Bouckaert *et al.* 2019) estimates the ARG together with other population genetic parameters under a Bayesian approach. Another software program to infer recombination networks is *SplitsTree* (Huson 1998), which has been frequently applied to analyze the evolutionary history of viruses (e.g., Castelhamo *et al.*, 2017). This tool includes several algorithms (based on traditional genetic distances) to efficiently infer phylogenetic networks and it includes a user-friendly GUI.

Analyzing Recombination in Sequences Derived From Next Generation Sequencing

Next generation sequencing (NGS, also known as high-throughput sequencing) allows an in-depth study of the diversity and structure of genomes, including virus genomes (e.g., Perez-Losada *et al.*, 2018; Marston *et al.*, 2013). However, the evaluation of recombination in sequences derived from NGS should be carefully performed because the assembly of reads may result in artifacts that create false positive recombination (Prosperi *et al.*, 2011; Zanini *et al.*, 2017). In order to account for this possible source of

error, a few complex strategies using experimental (e.g., [Laureau et al., 2016](#)) and computational (e.g., [Zhang, 2013](#)) methods have been proposed to estimate recombination from NGS data. However, methods to accurately estimate recombination from NGS data, including a proper evaluation and software implementation, are still demanded.

Illustrative Case Studies of Analysis of Recombination in Virus Genetic Data

The following case studies focus on why and how recombination was analyzed:

Recombination in the Design of HIV-1 Centralized Vaccines

Molecular evolution can allow viruses to escape from vaccine mediated immunity. In order to take into account this aspect, centralized sequences from HIV-1 have been explored to develop vaccines (centralized vaccines) ([McBurney and Ross, 2007](#)). These centralized sequences include consensus (CON, based on the abundance of nucleotide states) (e.g., [Ellenberger et al., 2002](#)), ancestral (ANC, sequence of the root of a phylogenetic tree) (e.g., [Doria-Rose et al., 2005](#)) and center-of-tree (COT, ancestral sequence at the place of a phylogenetic tree with the smallest evolutionary distance to the tip nodes) (e.g., [Rolland et al., 2007](#)) sequences. HIV-1 vaccines based on these centralized sequences were only partially effective in producing T-cell responses (e.g., [Frahm et al., 2008](#)). One of the possible causes of the incomplete immune response could be the computational inference of the centralized sequences ([Arenas and Posada, 2010a](#)). In particular, studies developing centralized HIV-1 vaccines inferred phylogenetic trees (required to obtain ANC and COT sequences) ignoring recombination, despite recombination being commonly observed in this virus ([Jetzt et al., 2000](#)). Ignoring recombination (if it is present) can lead to incorrect phylogenetic tree reconstructions ([Box 1](#)). In a previous study it was found that ancestral sequences inferred ignoring recombination (when it is present) display sequence errors that lead to HIV-1 epitopes and N-glycosylation sites [fundamental for the protein activity and predicted with the tool *ELF* (Epitope location finder), referenced in the section Relevant Websites] different to those derived from considering recombination ([Arenas and Posada, 2010b](#)). Altogether, future studies inferring centralized sequences should take into account recombination ([Box 1](#)).

The Influence of Recombination on HIV-1 Fitness Recovery

The specific influence of recombination on viral fitness has not been totally clear. Recombination can generate, but also break-down, better adapted variants ([Hadany and Beker, 2003](#)). While some studies found that variants derived from recombination overall present a decrease of viral fitness (e.g., [Bretscher et al., 2004](#)), other studies indicated the opposite (e.g., [Moradigaravand et al., 2014](#)). The influence of recombination on viral fitness was investigated by monitoring the fitness of several HIV-1 biological clones during an in vitro evolutionary process that included a large number of population plaque-to-plaque passages ([Arenas et al., 2016](#)). It was found that the fitness increase coincided with the increase of the recombination rate (estimated with *OmegaMap*), but not for all the studied clones. The conclusion drawn was that the fitness increase was driven by additional processes. Firstly, after recombination some mutations should have occurred to optimize the recombinant variant and further, a new recombinant variant requires enough frequency in the viral population to present a detectable effect on fitness ([Iglesias-Sanchez and Lopez-Galindez, 2002](#)). In addition, some clones increased fitness without requiring recombination. Altogether, the fitness effects of mutation and recombination events seemed to follow a heterogeneous and complex fitness landscape ([Lorenzo-Redondo et al., 2014](#)). When moving through the fitness landscape, a mutation event could lead to a small fitness variation (as a tuning) while a recombination event could imply a big change (i.e., generating a variant with a totally different fitness). In other words, the need for either mutation or recombination events could be related with the shape of the fitness landscape.

Recombination Among Hepatitis B Virus Genotypes

The Hepatitis B virus (HBV) presents a large diversity among its 10 so far detected genotypes (A-J). Interestingly, this virus has shown extensive recombination between genotypes (e.g., [Araujo, 2015](#)) where most of the recombinant forms (60%) include B/C and A/D hybrids [other recombinant forms include A/B/C, A/C, A/C/G, A/D, A/E, A/G, B/C/U (U = unknown genotype), C/F, C/G, C/J, D/E, D/F and F/G] ([Araujo, 2015](#)). The frequency of recombination was evaluated (through the recombination rate estimated with the program *RDP*) within each HBV genotype in more than 4700 HBV full genome sequences ([Castelhamo et al., 2017](#)). It was found that the recombination rate varied among HBV genotypes (genotypes B, C and E presented high levels of recombination while genotype G presented negligible recombination) and these differences could be explained by the epidemic and genetic characteristics of every genotype ([Castelhamo et al., 2017](#)). A recombination phylogenetic network was also inferred (with the program *SplitsTree*) showing the evolutionary relationships among HBV genotypes. The phylogenetic network could distinguish every genotype into a particular group and showed connections between genotypes. The network also presented recombination nodes within and among genotypes that quantitatively correlated with the estimated recombination rates (i.e., genotypes with high recombination rate presented a large number of reticulate nodes and vice versa).

Analyzing Adaptation of HIV-1 gp120 Under Recombination

The creation of an effective vaccine against HIV still remains as a challenging task (McMichael *et al.*, 2013). One of the multiple attempts made in the development of a vaccine against HIV consisted of a recombinant envelope glycoprotein subunit 120 (rgp120) vaccine (Flynn *et al.*, 2005). The vaccine was evaluated in more than 5000 volunteers and, unfortunately, it did not prevent HIV-1 acquisition. Interestingly, the results varied among volunteers according to ethnic groups [i.e., nonwhite volunteers showed a higher prevention of infection respect to other ethnic groups (further details in Flynn *et al.*, 2005)] and a possible cause could be differences in the immune system among these groups. This hypothesis was explored by analyzing the molecular adaptation (through dN/dS) of the gp120 viruses in hosts belonging to different ethnic groups (Perez-Losada *et al.*, 2009). Although this analysis should be straightforward by directly estimating dN/dS , the presence of recombination in the data was detected with the framework *HYPHY* (through its algorithm *GARD*). Note that recombination can bias the phylogenetic tree reconstruction and inferences derived, including the estimation of dN/dS (Box 1). Consequently, a methodology to estimate dN/dS was applied that considers the recombination breakpoints identified with *GARD*. In particular, the recombination fragments delimited by the recombination breakpoints were separately analyzed by inferring a phylogenetic tree specific for each fragment and by estimating dN/dS for each fragment accounting for the corresponding phylogenetic tree. The parameter dN/dS was estimated with well-established frameworks including *HYPHY*, *PAML* (Yang, 2007) and *SNAP* (Korber, 2000). The results showed differences of dN/dS in viruses from different ethnic groups, where in general the Black ethnic group presented a higher dN/dS (with values above 1 that suggested positive or diversifying selection) than other ethnic groups (including Whites, Hispanic and Asians, presenting values below 1 that suggested negative or purifying selection) (further details in Perez-Losada *et al.*, 2009). The results showed viral genetic consequences that could be derived from a different immune response among races and, consequently, multiple ethnicities should be taken into account to design future trials and vaccines.

Concluding Remarks

Recombination is a crucial evolutionary process in multiple viruses allowing a rapid adaptation to changing environments. The major importance of recombination motivated the development of a number of computational methods (together with software implementation) to analyze it in terms of evaluating its presence/absence, predicting breakpoints and estimating rates. However, only a few computational frameworks (especially those implementing a GUI) have been well-established in the field. In practice, estimates of recombination can disagree between frameworks and, for this reason, it could be interesting to find more studies evaluating the accuracy of the currently available frameworks (i.e., using expectations and computer simulations) in the analysis of typical DNA sequences under different levels of diversity and recombination. An attempt has been made to address this concern evaluating the recombination rate estimated with three frameworks (Lopes *et al.*, 2014) but a more comprehensive study is necessary.

In this article it has been highlighted that ignored recombination can bias the phylogenetic tree reconstruction and other evolutionary analyses based on such a phylogenetic tree (Box 1). However, in the bibliography one can easily find studies presenting recombination during the evolution of virus populations and phylogenetic tree reconstructions that ignore recombination. In this article two methodologies have been presented to properly perform a phylogenetic inference (and other evolutionary analyses affected by recombination) under the presence of recombination and it is recommended to apply them to formally avoid biases. Hopefully, future studies on Virus Evolution undergoing recombination will benefit from the technical information reviewed in this article.

This is an update of Alexander E. Gorbalenya, C. Lauber, Phylogeny of Viruses, Reference Module in Biomedical Sciences, Elsevier Inc., 2017, doi:10.1016/B978-0-12-801238-3.95723-4.

Introduction: Evolution, Phylogeny, and Viruses

Biological species, including viruses, change through generations and over time in the process known as evolution. These changes are first fixed in the genome due to selection or by chance (due to genetic drift or as a result of ‘founder effect’) that give rise to genetic lineages. Due to either limited fidelity of the replication apparatus copying the genome or adverse physico-chemical activity of the environment, nucleotides may be changed, inserted, or deleted. Genomes of other origin may also be a source of innovation for a genome through the use of specially evolved mechanisms of genetic exchange (recombination). Accepted changes, known as mutations, may be neutral, advantageous, or deleterious, and depending on the population size and environment, the mutant lineage may proliferate or go extinct. Overall, advantageous mutations and large population size increase the chances for a lineage to succeed. The fitness of a lineage is constantly re-assessed in the ever-changing environment and lineages that, due to mutation, became a success in the past could be unfit in new environments. Due to the growing number of mutations accumulating in the genomes that may repeatedly affect the same genomic position, lineages diverge over time, although occasionally, due to stochastic reasons or under similar selection pressure, they may converge locally.

The relationship between biological lineages related by common descent is called phylogeny; the same term also embodies the methodology of reconstructing these relationships. Phylogeny deals with past events and, therefore, it is reconstructed by quantification of differences accumulated between lineages. Due to the lack of physical fossils and (relatively) high mutation rates, the utility of phylogeny was considered limited in the application to viruses until the advent of molecular data and discovery of endogenous viral elements integrated into host genomes proved otherwise. Comparison of nucleotide and amino acid sequences, and, occasionally, other quantitative characteristics such as distances between three-dimensional structures of biopolymers, have been used to reconstruct virus phylogenies to different depths. Results of a phylogenetic analysis are typically depicted in the form of a tree that may be used as a synonym for phylogeny. For instance, the all-inclusive phylogeny of cellular species is known as the Tree of Life (ToL) (Fig. 1(A)). More recently, two techniques, networks and forests of trees, are used to illustrate the complexity of phylogenetic relations and the uncertainty of phylogenetic inference, respectively.

With few exceptions, virus phylogeny follows the theory and practice developed for phylogeny of cellular life forms. For inferring phylogeny, differences between the sequences of species members, assumed to be of a discernable common origin, are analyzed. If species in all lineages evolve at a uniform and constant rate, like clocks tick, their evolution conforms to a molecular clock model. The utility of this model in relation to viruses may be very limited. Rather, related virus lineages may evolve at different and fluctuating rates and some sites may mutate repeatedly, including reverse substitutions. As a result, reconstruction of a full record of change at all sites may be infeasible for the currently available methods and is associated with ever increasing uncertainty with each new mutation as the distance increases. Furthermore, the accumulation of inter-species residue differences may progress nonlinearly with the time elapsed. At present, our understanding of these parameters of virus evolution is poor and this limits our ability to assess the fit between a reconstructed phylogeny and the true phylogeny, with the latter practically remaining unknown for most virus isolates. This gap in our knowledge does not undermine the conceptual strength and utility of phylogenetic analysis for reconstructing the relationships between biological species including the origins of viruses.

The ultimate goal of virus phylogeny is reconstructing the relationships between ‘all’ virus isolates and species. For instance, cellular species form three compact domains (kingdoms) and their origin can be traced back to a common ancestor in the ToL, using either ribosomal RNA or a common set of single-copy genes. Such inference is not feasible for viruses due to their diversity and the lack of a universal molecular denominator (trait). Thus, reconstructing a comprehensive virus phylogeny may require comparisons that involve genomes of viral and cellular origins. This formidable task remains largely ‘work in progress’. In fact, most efforts in virus phylogeny are invested in reconstructing the relationships at the micro, rather than grand, scale and they focus on well-sampled lineages that have practical (e.g., medical) relevance. Most recently, due to the advent of high-throughput next generation sequencing (NGS) and metagenomics, phylogeny of distant relations to characterize diverse viromes and the entire virosphere has become an active area of research. Phylogeny itself or in combination with other data may provide a deep insight into virus evolution and diverse aspects of virus life cycles, including virus interactions with their hosts.

Our knowledge about contemporary virus diversity has been steadily advancing with new viruses being constantly described by systematic efforts as well as occasional discoveries. In addition, descriptions of viral integrations into host genomes grant insights into some historic viral diversity that may now be extinct. These developments indicate that only small fractions of the currently circulating viruses and those that went extinct have so far been unraveled and have become available for phylogenetic studies. In any case, the continuing virus discovery effort will help to further refine viral phylogenies and resolve relationships that are unresolvable with our current virus sampling.

Fig. 1 Phylogeny of nidoviruses in comparison to the Tree of life (ToL) using the most conserved single-copy orthologous proteins. Bayesian phylogenies under the WAG amino acid substitution model with rate heterogeneity across sites and relaxed molecular clock with log-normal distribution of nidoviruses (A) and ToL (B) are drawn to a common scale of 0.2 amino acid substitutions per position. Major lineages are indicated by vertical bars and names; arteri: *Arteriviridae*, mesoni: *Mesoniviridae*, roni: *Roniviridae*, toro: *Toroviridae* (*Tobaniviridae*, from 2018), corona: *Coronaviridae*. Support values at basal internal nodes are posterior probability support values. (C) Distributions of pair-wise patristic distances extracted from (A) and (B). The combined set of distances was normalized relative to the largest distance that was set to one. Figure adapted from Lauber, C., Goeman, J., Parquet, M.D.C., *et al.*, 2013. The footprint of genome architecture in the largest genome expansion in RNA viruses. *PLoS Pathogens* 9 (7), e1003500. including update of the family taxonomy as of 2020.

Tree Definitions

Species share similarity that varies depending on the rate of evolution and time of divergence. The entire process of generating contemporary species diversity from a common ancestor is believed to proceed through a chain of intermediate ancestors specific for different subsets of the analyzed species (Fig. 2). Typically, these ancestral sequences are estimated internally during the tree building process or are not required at all, depending on the method used. The relationship between the common ancestor, intermediate ancestors, and contemporary species may be likened to the relationship between, respectively, root, internal nodes, and terminal nodes (leaves) of a tree, an abstraction that is widely used for the visualization of this relationship (Fig. 2). Alignment of the contemporary sequences with the reconstructed tree side by side, like shown for the toy example in Fig. 2, may reveal the full chain of sequence changes that have happened during evolution which, however, is rarely the case for real data sets due to repeated substitutions and incomplete species sampling. Trees are also part of graph theory, a branch of mathematics, whose apparatus is used in phylogeny. Formally and due to a strong link between phylogeny and taxonomy, leaves may be called operational taxonomy units (OTUs) and internal nodes and roots, since they have not been directly observed, are known as hypothetical taxonomy units (HTUs). Nodes are connected by branches or edges.

The tree may be characterized by topology, length of branches, shape, and the position of the root (Fig. 3). The topology is determined by relative positions of internal nodes, including the root, and terminal nodes; it defines branching events leading to

Fig. 3 Tree types and pitfalls of phylogeny reconstruction. (A) Unrooted tree for five hypothetical viruses that was reconstructed based on their gene or protein sequences. Branch lengths represent the amount of genetic change between two viruses typically measured in units of substitutions per site. The direction of evolution is undetermined. (B) The tree for the five ingroup viruses in A was rooted using an outgroup (o). The direction of evolution is from left to right. (C) The same tree as in B but with branches calibrated to represent time. Note that time does not necessarily correlate with the amount of genetic change (for instance, compare length of the branch leading to the cluster joining i4 and i5 with that of the same branch in B). (D) The relative positions of three highly divergent lineages is unresolved by the phylogeny (polytomy). (E) The true relationship of four hypothetical sequences (top) is not recovered by the phylogenetic reconstruction (bottom) due to long branch attraction involving i2 and i3. (F) Phylogenetic trees (bottom) reconstructed for three adjacent genomic regions (top) are different with respect to the position of i2 which was subject to a recombination event in middle genome region.

acceleration of computing power (see also below). Distance methods are often designed to converge on a unique phylogeny by clustering, with none others being even considered. The unweighted pair group method with arithmetic means (UPGMA) in which a constantly recalculated distance matrix is used to define the hierarchy of similarities through systematic and stepwise merging of most similar pairs at a time was the first technique introduced for clustering. The neighbor-joining (NJ) method uses a more sophisticated algorithm of clustering that minimizes branch lengths, and is the most popular among distance methods.

Although different trees may be compared in how they fit a distance matrix, it is character-based methods that are routinely used to assess numerous alternative phylogenies in search for the best one in a computationally intensive process. Due to the calculation time involved, assessing all possible phylogenies is found to be impractical for data sets including more than 10 sequences; for larger data sets different heuristic approximations are used that may not guarantee a recovered phylogeny to be the best overall. There are two major criteria for selecting the best phylogeny using character-state based information through either maximum parsimony (MP) or maximum likelihood (ML). In MP analysis, a phylogeny with a minimal number of substitutions separating the analyzed species is sought. The ML analysis offers a statistical framework for comparing the likelihood of fitting different trees to the data under competing models of evolution with parameters including population size change and rate of mutation in search for one with the best fit. The latter approach is mathematically robust and its statistical power may also be used in combination with other techniques of tree generation. A Bayesian variant of the ML approach has gained popularity in recent years. It can utilize prior knowledge about the evolutionary process, like known substitution rates or clustering of species subsets or dates of species isolation, in combination with repeated sampling from subsequently derived hypotheses. The result of a Bayesian

Fig. 4 Comparison of phylogenetic results between three methods. Shown are unrooted NJ, ML and Bayesian trees reconstructed for the same dataset of 287 aligned VP1 protein positions of 93 polyomaviruses. The LG amino acid substitution model with site heterogeneity modeled by a gamma distribution with four categories, as selected by ProtTest, was used. In the Bayesian analysis, a relaxed molecular clock approach with log-normally distributed rate was applied. The trees are drawn to the same scale of average amino acid substitutions per site, as indicated by the bar in the middle. Note the considerably shorter branch lengths of the NJ tree compared to the other two trees. Robinson-Foulds distances measuring the topological differences between tree pairs are shown in gray.

analysis is thus a forest of trees that reflects the uncertainty associated with the reconstructed phylogeny and which forms the basis to derive a consensus tree and statistical support for its branches and other estimated evolutionary parameters. In phylogenetic analysis of viruses the dates of species isolation are often used to date the MRCA of the analyzed viruses under a Bayesian framework, while fossil information is routinely used to time-calibrate trees of cellular organisms. The use of endogenous viral elements integrated into host genomes as genetic ‘fossils’ for time-calibration of virus phylogenies has also been explored. Bayesian methods have the highest computational cost due to their sampling approach and thus show the lowest speed, while realization of the similarly advanced ML algorithm may be largely comparable in speed to distance methods, allowing for the phylogenetic analysis of very large data sets like genome-wide tree reconstructions of cellular organisms or many thousands of viruses.

One should keep in mind that different methods for phylogeny reconstruction can produce different trees, concerning both topology and branch lengths, for the same data set, although better agreement between ML and Bayesian trees is common, especially in respect to branch lengths (Fig. 4). None of the methods is considered superior to the other methods with respect to all aspects of phylogeny reconstruction, and which method to use under what circumstances is often a point of debate. A valid approach to gain further confidence in phylogenetic results is to apply several methods on the data and to only trust HTUs that are inferred by more than one method.

After a tree is chosen, it is common to assign support values to internal nodes through assessing the nodes’ persistence in trees related to the chosen tree. One particular technique, called bootstrap analysis, in which trees are generated for numerous randomly modified derivatives of the original data set, is most frequently used in distance-based as well as MP and ML analysis. Each internal node in the original tree is characterized by a so-called bootstrap value that is equal to the number of times a node appears in all tested trees. Although the relationship between bootstrap and statistical values is not linear, nodes with very high bootstrap values are considered to be reliable. In a Bayesian analysis, the support of internal nodes is quantified through posterior probability values.

If species evolve according to a molecular clock model, the root position in a tree could directly be calculated from the observed inter-species differences as a midpoint of cumulative inter-species differences. Alternatively, the root position may be assigned to a tree from knowledge about the analyzed species that was gained independently from phylogenetic analysis. Commonly, this knowledge comes in the form of a single or more lineages which are assumed (or known) to have emerged before the ‘birth’ of the analyzed cluster. These early diverged species are collectively defined as ‘outgroup’, while the analyzed species may be called ‘ingroup’ (Fig. 3(B) and (C)). Also, a tree may be generated unrooted, a common practice in phylogenetic analysis of viruses for which the applicability of the molecular clock model remains largely untested and reliable outgroups may not be routinely available (Fig. 4). In an unrooted tree, grouping of species in separate clusters may be apparent, although these clusters may not be treated as monophyletic as long as the direction of evolution has not been defined. These challenges are addressed by the development of new approaches that infer rooted trees without artificially restricting species evolution to a constant rate (known as relaxed molecular clock models commonly used within the Bayesian framework).

Virus phylogeny can be inferred using either genomes or distinct genes, and each of these approaches, standard in phylogenomics, may be considered as complementary. Under the first approach, genome-wide alignments are used for analysis. Due to complexities of the evolutionary process that may be region specific, reliable genome-wide alignments can routinely be built only for relatively closely related viruses whose analysis, however, may be further complicated by recombination events (see below). Using the second approach, genes with no evidence for recombination may be merged (concatenated) in a single data set that may

be used to produce a superior phylogenetic signal compared to those generated for distinct genes or entire genomes. For viruses with small genomes or for a diverse set of viruses, it is common practice to use a single gene to infer virus phylogeny. Although the results produced may be the best models describing evolutionary history of a group of viruses, the validity of this gene-based approach for the genome-wide extrapolation remains a point of debate. Recently, network methods were used to infer and depict evolutionary relationships of multigene virus genomes taking into account gene-specific sequence affinities.

When the gene tree is used as representing the phylogeny of the entire genome, an underlying most common assumption is that its topology but not branch lengths holds for different genomic regions in reflection of their coevolution with potentially different rates of substitution. This assumption may be violated due to several evolutionary processes, including orthologous gene exchange between (closely) related viruses, gene duplication and horizontal gene transfer (HGT), all involving one or another form of recombination, or incomplete lineage sorting. In phylogenetic terms, this violation may be revealed through incongruency of trees built for different genome regions (Fig. 3(F)). Trees may also become incongruent due to various technical reasons related to the size and diversity of a virus data set. These characteristics complicate interpretation of the congruency test, which is widely used in different programs to identify recombination in viruses. Other pitfalls of phylogenetic reconstruction include the inability to resolve basal branching patterns of highly divergent lineages (Fig. 3(D)) and the relatively close clustering of lineages that are only distantly related and do not form a monophyletic group in the true (unknown) phylogeny (Fig. 3(E)). The latter phenomenon is known as long branch attraction (LBA) and the phylogenetic artifacts produced by LBA are most frequently observed for isolated, that is, long branches in the tree which represent distant lineages with no close relatives known.

Applications of Phylogeny in Virology

Phylogenetic analysis is used in a wide range of studies to address both applied and fundamental issues of virus research, including epidemiology, diagnostics, forensic studies, phylogeography, origin, evolution, and taxonomy of viruses. The first questions to be answered during an outbreak of a virus epidemic concern the virus identity and origin. Answers to these questions form the basis for implementing immediate practical measures and prospective planning, enabling specific and rapid virus detection and epidemic containment, which may include the use and development of antiviral drugs and vaccines. Among different analyses performed for virus identification at the early stage of a virus epidemic, the phylogenetic characterization is used for determining the relationship of a newly identified virus with all other previously characterized and sequenced viruses.

Results of this analysis may be sufficient to provide answers to the questions posed, as regularly happens with closely monitored viruses that include most human viruses of high social impact, for example, influenza virus, human immunodeficiency virus (HIV), hepatitis C virus (HCV), poliovirus, severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) and others that belong to different species. For these viruses, there exist large databases of previously characterized isolates and strains that comprehensively cover the so far characterized natural diversity. Should a newly identified virus belong to one of the respective species, chances are that it has evolved from a previously sampled isolate or a close variant and this immediately becomes evident in the clustering of these viruses in the phylogenetic tree. Combining the results of gene-specific and genome-wide phylogenetic analysis allows one to determine whether recombination contributed to the isolate origin. For instance, recombination was found to be extremely uncommon in the evolution of HCV, but not for poliovirus lineages that recombine promiscuously, also with closely related human coxsackie A viruses, both of which belong to the same virus species of human enteroviruses known as *Enterovirus C*.

When an emerging infection is caused by a new never-before-detected virus, the phylogenetic analysis is instrumental for classification of this virus and in the case of a zoonotic infection, for determining the dynamic of virus introduction into the (human) population and initiating the search for the natural virus reservoir. This was the case with many emerging infections including those caused by Nipah virus, SARS-CoV, Middle East respiratory syndrome coronavirus (MERS-CoV), ebolavirus, and Zika virus. In the case of SARS-CoV, very limited sampling of the coronavirus diversity at the time, some uncertainty over the relationship between phylogeny and taxonomy of coronaviruses, and the complexity of phylogenetic analysis of a virus data set including isolated distant lineages led to considerable controversy over the exact evolutionary position of SARS-CoV among coronaviruses, does it prototype a new genus (group at the time) or not. Since then, the matter has fully been resolved but this experience illustrates some challenges in inferring virus phylogeny. That experience informed the subsequent classification of MERS-CoV and SARS-CoV-2, most recently.

The search for a zoonotic reservoir of an emerging virus may involve a significant and time-consuming effort that requires numerous phylogenetic analyses of ever-expanding sampling of the virus diversity generated in pursuit of the goal. In this quest, phylogenetic analysis canalizes the effort and provides crucial information for reconstructing parameters of major evolutionary events that promoted the virus origin and spread. For instance, intertwining HIV and simian immunodeficiency virus (SIV) lineages in the primate lentivirus tree led to the postulation that the existing diversity of HIV in the human population originated from several ancestral viruses independently introduced from primates over a number of years. Similar phylogenetic reasoning was used to trace the origin of a local HIV outbreak to a common source of HIV introduction through dental practice (known as 'HIV dentist' case). These are typical examples illustrating the utility of phylogenetic analysis for epidemiological and forensic studies.

Geographic distribution of places of virus isolation is another important characteristic relative to which virus phylogeny may be evaluated. This field of study belongs to phylogeography. The evolution of human JC polyomavirus provides an example of confinement of circulation of virus clusters to geographically isolated areas, represented by three continents. Identification of West

Nile virus in the USA illustrates a geographical expansion of an Old World virus into the New World. Analysis of phylogenies of field isolates of rabies virus of the family *Rhabdoviridae* sampled from different animals across Europe led to the recognition that interspecies virus expansion occurs faster when compared to geographical expansion.

Phylogenies can also reveal information about the relative strength of the virus–host association over time. In some virus families (e.g., the *Coronaviridae*) host-jumping events may be relatively frequent in establishing new species or diversifying existing species; they include the emergence of successfully circulating human coronavirus OC43 (HCoV-OC43), and repeated introduction of strains from the species *Middle east respiratory syndrome-associated coronavirus* (ongoing MERS-CoV epidemic) and *Severe acute respiratory syndrome-associated coronavirus* (SARS-CoV and SARS-CoV-2 pandemics) into the human population, the latter providing examples of two independent and temporally separated introductions of closely related viruses from the same viral species. At the other end of the spectrum one finds the family *Herpesviridae*. Extensive phylogenetic analysis of herpesviruses and their hosts showed a remarkable congruency of topologies of trees indicating that this virus family may have emerged some 400 million years ago and that herpesviruses largely cospeciate with their hosts. Likewise, members of the family *Hepadnaviridae*, which are reverse-transcribing small DNA viruses, are known for their strong host association and low frequency of cross-speciation events. Moreover, through phylogenetic analysis one can show that most viruses, and in particular RNA viruses, evolve at rates that are orders of magnitude faster than those of cellular organisms. For instance, even the most conserved enzymes encoded by nidoviruses, comprising only few RNA virus families, accumulated more than twice as many substitutions during evolution than their counterparts across the ToL, as estimated through branch lengths of the respective phylogenetic trees (Fig. 1). Taking into account that the MRCA of all cellular organisms likely predates the nidovirus MRCA, this reveals that most residues of viral proteins changed repeatedly and more frequently than cellular protein residues during long-term evolution. In fact, this high evolutionary rate seems to be a prerequisite for RNA viruses to stay fit in the ever-changing environment considering their tiny genomes that would otherwise not be able to produce enough genetic variation.

Phylogenetic analysis becomes increasingly important in virus classification (taxonomy), especially after the acceptance of genomic sequences by the International Committee on Taxonomy of Viruses (ICTV) as the sole basis of virus classification in 2017, which incorporated metagenomic sequences into the taxonomic framework. Viruses discovered by metagenomics now greatly outnumber viral genomes from reference databases. For viruses united in taxa above the genus rank, phylogenetic clustering for most conserved replicative and occasionally structural genes is commonly observed and has been used in the decision making process for many years. For instance, human hepatitis E virus, originally classified as a calicivirus using largely virion properties, was eventually expelled from the family *Caliciviridae* due to poor fit of genome characteristics, including results of phylogenetic analysis; it now forms a separate family *Hepeviridae*. Phylogenetic considerations also played an important role in establishing many new families, for example, the *Marnaviridae* and *Dicistroviridae*. Now these sequence-based analyses are transforming the taxonomy of large DNA phages which was, until recently, developed in such a way that existing families may have united phages with different gene layouts and phylogenies. Phylogenetic analyses of very distant relationships were used to populate the newly established ranks above the order rank, which prompted discussion about the reliability of such inferences. The interaction between phylogeny and taxonomy is dynamic and efforts were also made in extracting taxa and rank structures from monophyletic clusters in trees using analysis of pairwise evolutionary distances. In future, one might hope for important advancements of virus taxonomy that improve cross-family consistency in relation to phylogeny. Genome-based phylogenetic analysis offers a robust and systematic approach to incorporate these viruses into the taxonomy of viruses to foster their easy access and use by the research community.

What is up in Virus Bioinformatics

The virosphere may contain the greatest diversity known to mankind. It has been estimated that there are 10^{31} viruses on Earth, and for billions of years their ongoing proliferation and mutation has contributed to an unparalleled genomic diversity globally. Viral mutation rates range from 10^{-8} to 10^{-6} substitutions per nucleotide per cell infection for DNA viruses and from 10^{-6} to 10^{-4} substitutions per nucleotide per cell infection for RNA viruses. The only way to efficiently analyse this biodiversity is by applying powerful computational tools to (1) identify viral sequences and their encoded functional elements, (2) predict, annotate, and compare their functions, and (3) structure the data to move from measuring to understanding. Until recently, our full understanding of viruses was based on a few hundred viruses that were isolated and could be studied in detail. With recent bioinformatic developments, thousands of new viruses can be readily discovered in all natural and host-associated biomes (see also Section “Viral Metagenomics” below). Including these naturally occurring viruses in comparative analyses opens up possibilities for *de novo* computational predictions, including about the structure and function of viral genes.

Technology and Bioinformatics Drive Discoveries

The past decades have been characterized by technological innovations that revolutionized the way we do science, ranging from the development of computers and the internet, to high-throughput measurement technologies including DNA sequencing, mass spectrometry, and imaging. New fields were built based upon these developments, including bioinformatics, machine learning, and omics. These advances have expanded the scope in all scientific fields, not least in virology. One of the most profound impacts is a new view of the virosphere that is one of an unparalleled diversity. To illustrate, the number of recognized deep viral taxonomic groups has been greatly expanded and the International Committee for Taxonomy of Viruses (ICTV) has recently approved an expansion of the resolution of the viral taxonomy to 15 ranks: realm, subrealm, kingdom, subkingdom, phylum, subphylum, class, subclass, order, suborder, family, subfamily, genus, subgenus, and species.

Bioinformatic analyses of omics and other biological datasets depend on specialized computational tools. The development of these tools begins with basic analyses that are then incrementally used to create more complex applications. Examples of basic applications include software to validate the data derived from next-generation sequencing machines, build alignments of gene or protein sequences, and perform statistical tests. Higher-level analyses may include pipelines for metagenomic analysis, genome annotation, or genotype-phenotype association. Taken together, bioinformatics is arguably one of the subdisciplines in the life sciences with the broadest applicability. When calculated as the amount of computer time allotted to computational analyses, the largest consumer in virology is the analysis of omics datasets. Omics analyses are characterized as high-throughput, untargeted, and generally quantitative, and their application opens the door to systems level analysis of viruses and their effects on their hosts. For example, comparative genomics allows thousands of viruses to be analyzed, identifying important viral genes, their functions, and their evolution; metagenomics allows viruses to be discovered and identified with high throughput; and phylogenetics and phylogenomics allow new viral taxonomic groups to be identified. Some of these applications are presented and discussed in the article below.

Tools for Diagnostics

Viral infections can form a significant burden not only for human health but also for the health livestock and plants. The direct detection of viruses in clinical and other samples include microscopy, antigen detection such as ELISA, and molecular detection of the viral genomic material by PCR. Popular molecular diagnostic techniques including qPCR or RT-qPCR also allow quantification of viral loads. While these techniques are highly sensitive for the detection of specific viruses in a sample, they can only identify viral sequences that match a pre-defined search image that matches the designed PCR primers. Thus, these established diagnostic tests frequently yield negative results when a patient presents a clinical phenotype, but no virus is detected. This can be either because an uncommon variant of a known pathogen is present in the sample, or because a novel virus is the causative agent of the disease. Notably, the difference between these two possibilities is continuous, reflecting increasing evolutionary distances along the viral phylogeny.

Bioinformatic approaches allow PCR panels to be designed that capture an increasingly diverse array of viruses, but these assays will always remain limited to detecting viruses within a known range, and cannot extrapolate to identify completely novel ones. This may be resolved by untargeted (shotgun) sequencing of isolated viruses or complete sample DNA (metagenomics). Variants of

known viruses may be detected by aligning the reads derived from the sample to the reference sequence of the known virus that was originally used for designing the primers. If enough high-quality reads span the regions where the primer sequences should anneal with the target, specialized variant detection tools can call the variant with a high degree of confidence, and new PCR primers can be designed to capture them. For example, a recent PCR-based investigation of the widespread human gut-associated bacteriophage crAssphage designed globally applicable primers by screening an alignment of sequencing reads from a range of publicly available metagenomes and identifying highly variable regions of the appropriate size (1000–1400 nucleotides) that were flanked by conserved regions which could be targeted by primers, and were present in $\geq 90\%$ of all metagenomic samples ($< 10\%$ gaps). These primers allowed a range of collaborating laboratories to independently detect crAssphage in samples from 62 different localities on six continents. Detection of completely novel viruses from metagenomic datasets is less straightforward and will be discussed below.

Genome Sequencing

Obtaining the genome sequence of viral isolates is a highly standardized approach where second (massively parallel) and third (single molecule) DNA sequencing technologies have allowed immense progress. An important first step prior to any downstream analyses based on raw sequencing data is quality control. Several metrics can be used to estimate read quality. First, the sequencing machine provides quality scores for the individual nucleotides that estimate the probability that a nucleotide was wrongly measured. These are based on the logarithmic Phred scores and range from 0 (nucleotide measured with 0% accuracy) to > 40 ($> 99.99\%$ accuracy). Second, several heuristics have proven useful in the identification of potentially spurious sequencing reads that may be removed from the data, including the presence of any remaining primer, index, or adapter sequences, the over-representation of specific nucleotide subsequences (*k*-mers), divergent GC content, and the presence of duplicates of the sequence in the sequencing dataset. There is a wide array of bioinformatic tools that have been developed to calculate these metrics and produce quality reports that summarize the results in useful graphical interfaces, such as FastQC, multiQC, and PRINSEQ (Table 1). Once potential issues with the data have been identified, short read sequences can be pre-processed to eliminate these sources of technical variation or errors. Typically, bases that fall under a set threshold are trimmed off along with any leftover primer or adapter sequences. Depending on the downstream application, remaining reads shorter than a length threshold are also discarded. Alternatively, dedicated tools can perform error correction on the short reads themselves.

An additional step that is specific for viral datasets is the removal of any remaining host sequences. If a genome sequence of the host is available, host-derived reads may be detected by mapping the reads against the host genome. Reads that confidently map to the host may be removed to ensure that the remaining part of the read set reflects the viral fraction of the sample. In the clinical context and for human patient samples, in particular, removal of reads mapping to the human reference is essential in order to abide to established international guidelines for safeguarding the individual's privacy. Correct identification of viral sequences that might have integrated in the host genome, as is the case with retroviruses and prophages, still remains a challenge. In these cases, viral reads may still align to the sequences of proviruses or prophages in the host genome if they are sufficiently similar, and may thus be removed from the sequencing dataset. Potential solutions include masking these proviruses in the host reference genome, or postprocessing the removed putative host reads by comparing them to another database of known viral sequences that includes the sequences of the integrated viruses. Detecting integrated viral sequences in the genome sequences of cellular hosts, and accurately determining their integration boundaries remains an ongoing bioinformatic challenge.

A typical sequencing effort targeting a viral genome with current second generation sequencing technologies will result in millions of short sequences of the order of $\sim 10^2$ nucleotides in length. Typically, these sequencing reads are generated from random fragments of the genome or genomes in the sample (hence the term “shotgun sequencing”). Because viral genomes range from $\sim 10^3$ – 10^5 nucleotides, for most practical purposes these short reads need to be assembled, unless a very closely related reference genome sequence is available. Sequence assembly is the process whereby short reads are combined into longer stretches of contiguous sequence (contigs). In case a single non-segmented genome is assembled, the end result optimally consists of a single string of nucleotides representing the complete genome sequence. Since most viral genomes are smaller and simpler in their structure than those of cellular organisms, assembling a full viral genome is relatively straightforward. Still, sequencing errors, repetitive and low complexity regions, and especially quasispecies diversity that results from high mutation rates may pose specific hurdles into obtaining a complete genome sequence. Several virus specific genome assemblers have been developed to address these issues including VICUNA and IVA (Table 1).

The latest advances in long read sequencing technologies promise high quality viral genomes. Recently, long read sequencing was shown to allow whole viral genomes to be captured in a single read, for example by direct sequencing of influenza and coronavirus genomes. Long read sequencing technologies still come with a higher error rate than their short counterparts. Hybrid approaches leveraging the advantages of long reads (ability to span low complexity and coverage regions) and short reads (low error rates) produce high quality, full viral genomes. Successful long read-based genome assemblies have been reported for the human cytomegalovirus and the pig pseudorabies virus. In principle, similar pre-processing steps apply to long as to short sequencing reads, but dedicated tools are used that take into consideration their specific limitations. Extensive quality summaries can be obtained with Poretools or nanoOK. The relatively error-prone long-read sequencing data may be corrected either without the use of additional short-read sequences (i.e., non-hybrid) or with a hybrid approach. Examples of tools performing non-hybrid error-correction include Nanocorrect and PoreSeq, while hybrid methods include Nanocorr and NaS. Similarly, non-hybrid assemblers include Canu and Miniasm, with SPAdes and Unicycler performing hybrid assemblies.

Table 1 List of selected software tools and resources for virus bioinformatics tasks

Read processing tools		
<i>Quality check</i>	FastQC, PRINSEQ, mulitQC Poretools, nanoOK	Checks read sequencing quality Quality checks for nanopore long reads
<i>Raw reads pre-processing</i>	Cutadapt, Trimmomatic, BBduk Nanocorrect, PoreSeq Nanocorr, NaS	Quality trimming, artefacts removal on short reads Non-hybrid error correction for nanopore long reads Hybrid error correction for nanopore long reads
Genome assembly tools		
<i>Single genomes</i>	VICUNA IVA SPAdes Canu, Miniasm Unicycler	Produces population consensus genome assembly Assembler designed for RNA viruses Generic genome assembler Non-hybrid assemblers for nanopore long reads Hybrid assembly pipeline for nanopore long reads with the use of short reads
<i>Metagenomes</i>	MEGAHIT, metaSPAdes, Ray-meta, IBDA-UD crAss	Assemblers optimized for metagenomics data Cross-assembly analysis of multiple metagenomes
Read mapping		
	BWA, Bowtie, BBmap STAR GraphMap, LAST	Align short read sequences to a reference Splice-aware aligner for RNA-seq data Align long read sequences to a reference
Gene Prediction		
	ORF Finder Prodigal VIGOR	Searches for open reading frames in the provided sequence A protein-coding gene prediction software tool Annotation program for small viral genomes
Similarity searches		
	BLAST HHpred HMMER	A suite of tools to find regions of similarity between DNA and protein sequences Sensitive protein homology detection, function, and structure prediction Homology based search
Multiple Sequence Alignment		
	MAFFT, ClustalW MUSCLE	Multiple sequence alignment for DNA and protein sequences Multiple sequence alignment for protein sequences
Sequence taxonomic annotation		
	CAT, Kraken, Centrifuge, Kaiju	Assign taxonomic labels to reads or assembled contigs
Phylogenies		
	RaxML, PhyML BEAST	Inference of large phylogenetic trees A software package for phylogenetic analysis with an emphasis on time-scaled trees
Taxonomy and classification		
	GRAViTy vConTACT VICTOR DEmARC	Classification of eukaryotic viruses Classification of double stranded DNA viruses of bacteria and archaea Genome based phylogeny and classification of prokaryotic viruses Classification of viruses based on genetic divergence
RNA secondary structures		
	mfold/UNAFold ViennaRNA package LocARNA	RNA secondary structure prediction Suite of tools to perform RNA structures prediction and comparison Structure-guided multiple sequence alignment of RNA sequences
Transcriptomics		
	DESeq2, Sleuth	Statistical analysis of RNA-seq data
Databases		
	ViralZone Virus Variation Resource Virus Pathogen Database and Analysis Resource (ViPR)	Link specific knowledge for each virus family with viral protein and genomic sequences A community portal for viral sequence data An integrated repository of data and analysis tools for multiple virus families

After genome assembly, annotation is an important computational analysis that is required for interpreting the functionality of the virus in its environment. This includes a prediction of functional features such as protein-coding genes and tRNAs, and a classification step where each feature is characterized by similarity to known proteins or RNAs. Importantly, most genes predicted from novel viruses are distant from known references, and common similarity detection tools like BLAST often cannot provide relevant information in this context. Conversely, the use of more sensitive tools relying on the detection of conserved residues and the representation of protein sequence diversity as Hidden Markov Model (HMM) profiles (e.g., HMMER, HH-PRED, PSI-BLAST), is much more useful when analyzing novel virus genomes. These tools are able to detect distant homologies between distantly related viral proteins, which is often the only way to detect homology and, consequently, suggest potential functions in the light of the rapid viral sequence evolution.

RNA Secondary Structures in Viruses

RNA secondary structures play an important role in the life cycle of viruses, especially RNA viruses. These are formed either via the interaction of nucleotides located at close proximity to each other or at distances of several thousand bases (i.e., long-range RNA-RNA interactions, LRI). Local RNA structures were shown to be involved in translation initiation in Hepacivirus and Tombusvirus, while LRIs between the 5' and 3'-UTRs of *Flaviviridae* family genomes promote replication. Moreover, a network of intra- and intersegment RNA-RNA interactions facilitates reassortment between Influenza A genomic segments from different co-infecting strains. This genomic reshuffling may have important effects, including the loss of vaccine efficacy.

Current algorithms for *in silico* prediction of RNA secondary structures mainly employ thermodynamic methods and can be applied to single sequences with software tools like mfold or its successor UNAFold. Furthermore, functional RNA secondary structures are conserved among different viral strains and species and it has been shown that this conservation is higher on the structure level than on the sequence level. Improved bioinformatic methods for *in silico* predictions use several different sequences and their covariances. These covariances, originating from different viruses, are used to generate structure-guided multiple sequence alignments and increase the accuracy of these predictions. Such approaches have been implemented in tools like LocaRNA. Both single and multiple sequence-based predictions can be made using various tools included in the ViennaRNA package.

The *in silico* prediction of structures is limited by some assumptions of the underlying models. First, unpaired regions of two (or more) structures that interact with each other (i.e., pseudo-knots) are usually neglected. Second, the length of the input sequence is limited. The number of all possible structures increases exponentially with the length of the RNA sequence. In other words, the longer the sequence, the less confident the *in silico* prediction. Third, interaction sites that do not follow the canonical base-pairing model are usually not included in the prediction algorithms. New specific tools and analysis pipelines are constantly being developed and existing ones improved, in order to address known challenges. *In vitro* or *in vivo* validation of the presence of predicted structures in viruses and their biological function is of paramount importance. To this end, the close cooperation of virologists and bioinformaticians is indispensable for achieving new knowledge in the field of secondary structures in viruses.

Viral Metagenomics

Recently, a new source of viral genomic sequences has become increasingly important. Metagenomics samples genomic material directly from the environment, allowing for the reconstruction of complete viral sequences without cultivation. Early metagenomes did not allow for the assembly of large genome fragments, mostly because of a limited capacity in sequencing depth and assembly software available at the time. Hence, most analyses focused on individual marker genes or global comparison between datasets, i.e., “all-versus-all” similarity. While providing important information on the overall genetic diversity of viruses, these gene-level analyses suffered from major limitations. Specifically, gene-based approaches can only target specific groups of viruses since no universal viral marker gene exists and are thus limited in their ability to discover novel viral diversity and draw inference at the scale of whole viral communities.

An early database independent tool for cross-metagenomic comparison at the level of sequencing reads was crAss, for cross-Assembly, an approach that exploits sequence assembly to identify shared elements in different metagenomic samples. Greater sequencing depth per sample and improved bioinformatics now enable the assembly of large genome fragments and even complete genomes from metagenomes. These genomes, termed “uncultivated virus genomes” to distinguish them from genomes obtained from virus isolates, are now becoming the primary unit of most virome analyses. The community has thus recently established a set of standards and guidelines to identify, analyze, and report these genomes of uncultivated viruses in a manuscript entitled “Minimum Information about an Uncultivated Virus Genome (MIUViG)”, so that these sequences can contribute to a comprehensive mapping of viral diversity on Earth. In addition, the different tools commonly used in virus genome analysis are progressively being made available on free online data analysis platforms so that all researchers can incorporate uncultivated virus genomes into their analysis.

One of the areas that strongly depends on a thorough understanding of uncultivated viruses is viral ecology. Briefly, the first step in the analysis of viral diversity from metagenomics is to identify which of the assembled sequences are derived from viral genomes.

This step is required even when processing purified viromes, where most of the data is expected to be viral, because these can still contain a substantial fraction of contaminating cellular sequences. The second requirement is to evaluate whether an assembled contig corresponds to a fragment of a larger genome, or represents the majority and possibly the entirety of a genome sequence. This information is critical to correctly interpret these data, especially for analyses such as functional potential and taxonomic classification of the identified viruses. The current standards, comparable to the ones used for uncultivated genomes of bacteria and archaea, comprise three categories defined based on estimated genome completeness and the level of genome annotation provided: “genome fragments” are sequences representing <90% of the full genome, “high-quality draft genomes” represent $\geq 90\%$ of the genome with minimal functional annotation, and “finished genomes” are complete genomes with comprehensive annotations of the encoded functional elements. When these considerations are addressed, the relative abundance of different viral groups can then be assessed through “read mapping”, i.e., the reads sequenced in a metagenome are compared to the viral genomes, and the number of reads matching each genome is interpreted as a measure of the number of copies of this genome in the initial sample. Using this approach, traditional microbial ecology approaches can be applied to assess alpha and/or beta diversity of the viral community. Moreover, species-species interaction networks can be inferred based on the correlation of viral and/or microbial groups across samples, where network nodes reflect species and edges reflect their correlated abundance or occurrence patterns across samples. Thus, these networks summarize the information in individual metagenomes that represent temporary or spatial snapshots of ecosystems. Network-based approaches have been applied in the study of viruses and the interactions with their potential hosts, but their interpretation remains challenging. Nevertheless, they can help elucidate temporal and spatial dynamics of viral diversity as well as unravel the role of viruses in important ecological processes such as the carbon cycle.

The application of metagenomic deep sequencing and *de novo* assembly for virus diagnostics allows also distantly related viruses to be identified, provided that sensitive homology detection tools are used. The unbiased, high-resolution view of the viral diversity present in a sample that is offered by metagenomics, allows the identification of viruses in patient samples directly through agnostic sequencing. Advances have been made towards the application of metagenomics outside of the research context and into the clinic, with a growing number of studies evaluating metagenomics as a tool for animal and zoonotic diseases detection. These include discoveries of new viruses associated with deaths after organ transplantations in humans, polyomaviruses associated with Merkel cell carcinomas, encephalitis-causing viruses in cattle and other difficult-to-diagnose cases. However, these studies often reveal an array of viruses in most samples, and predicting for each of them whether they impact on human health remains an unresolved issue. There is still some ground to be covered for metagenomics to be established as a routine diagnostic test. Decreasing sequencing costs, improvements in the underlying bioinformatics tools, as well as standardization of protocols and well-defined guidelines for laboratory personnel will render this option even more viable in the future.

Evolution and Phylogenetics

Phylogenetic inference based on molecular data starts with the alignment of multiple homologous sequences that allows mutations to be identified. Next, several approaches exist that transform the knowledge of the identified mutations into a phylogenetic tree, including distance-based approaches like neighbor-joining that can be rapidly calculated, and more advanced approaches that build reliable phylogenetic trees based on an evolutionary model, including maximum likelihood or Bayesian optimization. Established statistical and mathematical models of evolution and the estimation of parameters such as substitution rates, divergence times, and other population genetics patterns are incorporated in various bioinformatic software packages such as RAXML, BEAST, and PhyML that are widely used in virus bioinformatics (Table 1).

Phylogenetic analyses of viruses encounters several challenges. First, efforts to reconstruct the “deep phylogeny” of viruses are hampered by the inability to calculate genetic distances between the highly divergent sequences of distant families. Thus, phylogenetics and phylogenomics are most successful in the context of narrowly defined groups of related genomes, whose members share a set of core genes that allow all members to be compared in a common framework. For example, the gene encoding the RNA-dependent RNA polymerase (RdRp) is the only universal gene among RNA viruses and phylogenetic reconstructions based on this have shed light into the origins and evolution of the global RNA virome. Second, phylogenetic trees of different viral genes often yield inconsistent phylogenies due to the high frequency of genomic recombination in viruses. Conventional phylogenetic trees used for graphically representing viral phylogenies are challenged by variable evolutionary rates, lack of physical “fossil records” of viruses, confounding evolutionary relationships between viruses and their hosts, high rates of horizontal gene transfer and rampant genomic rearrangements. An alternative approach to visualizing distant relationships are genome-level networks. In this context, network nodes represent virus genomes and edges are drawn between them if they share at least one gene. Using formal analytical tools the network topology can be interrogated. Such analyses have given insights in host range of phages. Furthermore, bipartite networks may also be used to depict the links between homologous gene families and genomes.

One application of phylogenetics in virology is the study and tracking of transmission networks and epidemics. Understanding the relationships between viruses can provide us with a wealth of information about when, where and how viruses are transmitted, and in what ecological or clinical context. Phylogenetic analyses can be employed to infer phylogenetic relationships between different strains, such as building a clearer picture of a viral outbreak or for the reconstruction of the demographic history of the pathogen. Transmission networks allow the analysis of evolutionary trajectories of very recently diverged strains of the range of less than years thanks to high viral mutation rates. This enables near real-time monitoring of virus outbreaks, as was shown in the

2013–2016 West African Ebola outbreak that was monitored “live” by nanopore sequencing of 142 Ebola virus genomes from patients in Guinea. Moreover, geographic mapping of 1610 Ebola virus genomes allowed the dispersal, proliferation and decline outbreak to be analyzed, revealing a heterogeneous and spatially dissociated epidemic consisting of different transmission clusters. In an epidemiological study of the 2013–2014 Zika virus outbreak in the Americas, molecular clock estimates suggested that its introduction into Brazil predated the 2014 World Cup soccer tournament and a canoeing event, potentially pointing to its introduction during the 2013 Confederations Cup soccer tournament. The integration of genomic, epidemiologic, and mobility data has led to the blossoming of the field of phylodynamics.

Another important application of phylogenetics in virology is taxonomy. Virus taxonomy is a field in flux. No standard automated viral taxonomy framework currently exists, but several computational tools have been developed that allow clustering of viral sequences and objective demarcation of the boundaries between taxonomic levels, such as DEmARC, vConTACT, VICTOR, and GRAViTy. In this context, the ICTV is now exploring genome-based taxonomy methods for different types of viruses, which would enable an integration of high-quality and finished metagenome-assembled virus genomes in the official taxonomy, and thus a better representation of viral diversity in the official ICTV classification. Taxonomic classification is grounded in phylogenetics, and different phylogenetic characters are suitable for distinguishing recent and ancient taxonomic groups, in accordance to their rates of evolution. The emerging consensus is that gene content methods similar to those developed in the beginning of the genomic era for cellular organisms are the method of choice for resolving ancient taxa. For defining recent taxa, alignment-based methods are appropriate for taxa with widely shared marker genes.

Virus-Host Interactions

In 1973, an early breakthrough in the understanding of co-evolution came with the definition of a law known as Red Queen, named after the Alice in Wonderland character. Applied to viruses, the law describes a co-evolutionary steady state in which hosts evade the viruses that infect them by mutating certain interaction molecules, while viruses also mutate to retain virulence. Thus, for both parties “it takes all the running [in genome sequence space] they can do, to keep in the same place”. Both viruses and their hosts have evolved evolvability mechanisms that boost mutations in genomic regions containing important genes involved in virus-host interaction. For example, some bacteria and bacteriophages encode mechanisms of targeted genomic hyper-variation that diversify receptor-binding proteins (RBPs). Others encode genomic islands that contain proteins involved in cell decoration, or anti-phage defense systems that may be readily gained and lost from the genome. These and other mechanisms of accelerated evolution, combined with rapidly fluctuating selection pressures, make virus-host interaction genes among the most variable elements of bacterial and phage genomes.

Traditionally, viruses were always discovered and analyzed in the context of a host, either because the host showed symptoms of the viral infection, or because the viruses were isolated by growing them in a cell culture of their host. This has changed with the advent of metagenomics, as viral genomic sequences can be identified directly from their environment (see also Section “Viral Metagenomics” above). The direct sampling of viruses without host information complicates the interpretation of the ecological roles of viruses, including fulfillment of Koch’s postulates in the case of samples from diseased organisms. Thus, host prediction is an important current challenge in understanding the role of viruses identified from metagenomics. Metagenomics may reveal sequences that are distinct from those of known viruses; thus, their hosts cannot be predicted based on similarity to viruses that have been experimentally characterized. Recent advances in machine learning hold promise for predicting virus-host interactions, including several approaches that are based on the genome sequences alone. These approaches exploit genomic signals including, for example (1) the nucleotide usage profile of the genome sequence that is adapted in viruses as a result of co-evolution with their hosts; (2) regions of sequence similarity between virus and host genomes, which could reflect integrated proviruses, horizontally transferred genes, or other mechanisms; (3) CRISPR spacers in the bacterial genome matching the genomes of bacteriophages that infected that host lineage in the past; and several other signals. Nevertheless, most virus genomes assembled from metagenomes remain without any predicted host at this point, and designing new approaches to establish these linkages remains a major computational challenge in the field.

Machine Learning as an Opportunity

As new technologies allow diverse aspects of biological systems to be measured at unprecedented scale and resolution, the rapidly increasing complexity and dimensionality of the data are increasingly challenging to interpret. Emerging analysis and processing methods based on machine learning have the ability to deal with such large, complex data sets. The main power of such approaches is their ability to identify signals and patterns in the data, enabling predictions to be made by using statistical models. Machine learning describes the process of gaining general knowledge to effectively perform a specific task by analyzing samples.

Machine learning algorithms can be divided into different types based on their strategy and the kind of problem they address, primarily including supervised and unsupervised machine algorithms. Unsupervised learning algorithms analyze high-dimensional input data for patterns without a search image. This information can be extracted by clustering the input data and can be used to determine the importance of each dimension of the input data. Common approaches including PCA and t-SNE do

this by reducing the dimensionality of the input data while preserving the information. This can lead to insightful visualizations of clusters or patterns in complex data. For example, the k-means clustering algorithm is an unsupervised method that clusters the data into k different groups. This is achieved by combining the samples with the highest similarities into one group. If clear clusters are observed, this indicates variations in the data that may need further analysis before drawing general conclusions about the complete dataset. This can help to identify potential pitfalls of an experiment represented in the data. In contrast to unsupervised learning, supervised learning approaches like random forest, gradient boosting trees and support vector machines analyze features of the input data for solutions that correspond to a pre-defined pattern represented by training data. In a genomic context, such features could include the length of the genome sequence, the amino acid distribution of the encoded proteins, the age of a sampled patient, etc. From the methodological perspective, a feature can be any property of the data that can be numerically or categorically represented. The machine learning algorithm analyses the predefined features of each sample and searches for similarities which help to solve the predefined task. The predefined task is the transformation of the input data to the desired output data. For example, given a metagenomic sequence as input, a supervised machine learning algorithm could determine whether it is derived from a virus.

A major challenge in supervised learning is to identify generalizable patterns that are predictive of new “unseen” cases. To assess the performance of such algorithms, it is good practice to split the full dataset into three parts, including (1) training data that is used to identify significant patterns; (2) validation data that is used to optimize the parameters of the machine learning algorithm; and (3) testing data that is used to assess the performance of the approach on unseen data. For fair comparison, it is important that the testing data is in no way used to tweak or optimize the procedure. The amount of data used for training, validation, and testing may differ, but could represent e.g., 80:10:10 ratio, where it is important that the data points represent independent measurements. This may be especially challenging when predicting virus-host interactions (see Section “Virus-Host Interactions” above), because the viruses with known hosts that are present in the database are highly skewed for a few well-described groups. If left unaccounted for, this database bias leads to inflated performance statistics for virological machine learning predictors.

Recently, representation learning methods have gained a lot of attention due to their extraordinary ability to represent complex information in statistical models. Approaches including deep learning and transfer learning have the advantage that very complex data can be analyzed and processed, with only a minimal requirement for the user to define features. Such approaches are ideal for analyzing big omics scale datasets, but require large amounts of training data and concomitantly heavy computing power, orders of magnitude more than the classical approaches. To summarize, machine learning enables us to analyze, understand, and evaluate the huge amounts of data that are becoming available through technological innovations.

Host Transcriptomics

Viruses only come to life after infecting their cellular host. Understanding the host response is of utmost importance for the investigation of viral infections. Once the virus enters the host system (either a living organism or a virus-responsive cell line), highly specific regulators identify the threat and then stimulate the expression of a cascade of genes. For example, in the case of an RNA virus infection, antiviral type I interferons (IFN- α /beta) bind to their receptors, thus activating specific transcription factors and promoting the expression of several IFN-stimulated genes (ISGs) with antiviral and immunomodulatory activity.

Today, transcriptomics (RNA-Seq) is widely used to study the host response to viral infections. To this end, total RNA extracted from, e.g., uninfected (mock) and virus-infected host cells can be reverse transcribed into cDNA (complementary DNA), fragmented, and sequenced. Short-read sequencing technologies generate a high-resolution expression profile consisting of millions of short sequencing reads that represents the composition and relative amount of RNA molecules, together making up the transcriptome. Different computational approaches are combined to build bioinformatics pipelines to process and analyze these short-read data comprehensively. In the case of an available host (or closely related) reference genome, the reads can be mapped back to identify their origin and thus the origin of their corresponding RNA expression.

If no reference genome is available, RNA-Seq data can also be assembled *de novo* and subsequently characterized, to identify differentially expressed genes. A promising avenue in transcriptomics are long-read sequencing technologies such as offered by PacBio Iso-Seq and Oxford Nanopore technologies. The latter has already been used for sequencing and investigation of full-length host and virus transcripts in their native RNA form.

A gene that is more strongly transcribed during viral infection statistically yields a higher number of short reads after sequencing. Therefore, RNA-Seq not only allows the identification of transcribed host genes but also provides a quantitative value. The number of reads of the same gene derived from different conditions (e.g., mock versus infected) can be compared to identify differentially expressed genes. After normalization (taking into account different sequencing library depths and/or gene lengths), fold changes and their significance are calculated for each gene and between replicated conditions. To this end, tools such as DESeq2 and Sleuth, provided as R packages, are used to statistically evaluate the quality checked, mapped, and quantified RNA-Seq data. **Fig. 1** shows an exemplary RNA-Seq bioinformatics pipeline for the calculation of differentially expressed genes between mock, IFN-treated, and virus-infected cell lines of a microbat species (*Myotis daubentonii*) at two different times after treatment. Since no genome of this bat species was publicly available, the genome of a close relative (*M. lucifugus*) served as a reference for mapping and quantification.

Fig. 1 Overview of an RNA-Seq bioinformatics pipeline for the identification of differentially expressed genes based on a study of an IFN-treated and virus-infected (RVFV Clone 13) bat cell line (*Myotis daubentonii*). Samples were taken in triplicates at two time points and sequenced with Illumina. Reference genomes for the virus and a close relative bat species were obtained from NCBI and Ensembl, respectively.

Conclusions

Computers are not only indispensable to analyze data in virology, but also to store and distribute the large volumes of data generated in a reproducible way. Efforts into making the unprecedented amounts of data Findable, Accessible, Interoperable and Reusable (FAIR) should also be applicable in the field of virology. Several resources are currently available that are dedicated to viral specific sequence information and their associated metadata (Table 1). Currently, most analyses require a reference database, be it sequence based similarity searches for the identification of viruses, functional annotation of protein sequences or genome based phylogeny and classification. Making data publicly available in databases is important, not only as part of their general interest. As new methodologies are being developed, the available data can be further mined or reanalyzed to extract new information. A prominent example is the discovery of a highly abundant phage in the gut of humans, crAssphage; another is the recent suggestion that small circular single-stranded DNA smacoviruses infect Archaea instead of humans. The timely deposition of genomic data and their availability to the public domain is also crucial in the epidemiological context where this information can be used for continuous surveillance, designing effective diagnostics, vaccines and antibody-based therapies.

Bioinformatics opens up a vast range of possibilities for new analyses and interpretations of viruses. While computational predictions always need to be validated by relevant *in vitro* experimental follow-up, the unprecedented availability of big omics datasets in the public domain already allow bioinformaticians to perform many initial validations *in silico*. These best practices can be used to estimate the accuracy of diverse bioinformatics tools, providing an important focus for wet laboratory experiments and saving valuable time and resources. Thus, bioinformatics has already become an integral and transformative component of virus research, much like techniques such as culturing, microscopy, and molecular biology have done in the past.

Glossary

Metagenomics The study of genetic material (DNA or RNA) extracted from an environmental sample. Recent studies use “shotgun” metagenomics, i.e., the untargeted sequencing of all genomes from all members in the sampled community.

Viromics Viral metagenomics, i.e., shotgun metagenomics applied specifically to the encapsidated fraction of DNA and/or RNA from a sample. The encapsidated fraction is typically obtained through a combination of filtration, precipitation, and DNase/RNase treatment.

Metagenomics Applied to Viruses

Historically, viruses have been primarily explored using laboratory cultivation: new viruses were obtained from clinical or environmental samples through propagation and isolation on cell cultures. This process is, however, biased and challenging to apply at large scales because (i) many viruses depend on host cells that are difficult to maintain as clonal culture in the laboratory, and (ii) even if the cells are available, propagating viruses may require specific conditions distinct from those used to cultivate the cells. These considerations are especially meaningful for viruses with microbial hosts, the vast majority of which remain uncultivated to date.

Metagenomics bypasses this requirement for cultivation and instead relies on the sequencing of viral genomic material extracted directly from a sample (see [Box 1](#) and [Fig. 1](#)). Thus far, the history of viral metagenomics has seen two major phases. Initially, entire communities of viruses were assayed by analyzing and comparing short sequencing reads obtained from diverse environments. Because of the fragmented nature of these data, most of these studies had to be conducted at the community scale, and identifying and distinguishing individual viruses in these datasets remained challenging. More recently, bioinformatic advances have enabled the reconstruction of individual viral genome sequences from metagenomes, allowing naturally occurring viruses to be identified and studied at high, genomic resolution. Using a metagenomics approach, entirely new types of viruses can now be discovered, surveyed, and characterized even without cultivation. The unique ability offered by metagenomics to study uncultivated viruses led to the emergence of two parallel and interconnected fields: a clinical one, where metagenomics promises to be a catch-all method for the unbiased surveillance and diagnosis of viral pathogens, and one focused on natural biomes, that aims to describe the diversity of the viral world and understand its ecological and evolutionary drivers and impacts.

Pioneering Viral Metagenomics, One Gene at a Time

When the field of shotgun environmental metagenomics was pioneered in 2002 by the laboratory of Forest Rohwer at San Diego State University, the first datasets consisted of three viral metagenomes (viromes) that, together comprised just under 2,500 short genomic fragments derived from two natural marine viral communities and one human feces sample. While limited in scope and resolution, these and other early viromes provided an unprecedented view of complex viral communities in nature. Both oceanic and human fecal viromes pointed toward the existence of an extensive virus diversity. This diversity of the virosphere was estimated by comparing the sequencing reads within each metagenome, and observing that almost every fragment was unique. Moreover, comparing the short sequencing reads to a reference database of known viral genomes sequences revealed that up to 99% was not similar to any known virus, suggesting that most of the virosphere was yet to be discovered. This uncharted genomic biodiversity became popularly known as “viral dark matter”.

In the years that followed, a broader range of environments was progressively surveyed using viromics including freshwater lakes, hot springs, agricultural soils, or human skin, saliva, and gut samples. Improvements in DNA sequencing technologies, especially the advent of the popular pyrosequencing platform, that has since been surpassed and discontinued, increased the scale of these datasets by providing hundreds of thousands of short genomic fragments for each sample. By directly comparing the sequences across these datasets, several studies indicated that virus genes tend to structure by environment rather than by sample location, implying that some of these genes may be globally distributed. In addition, when sampled from the same freshwater and hypersaline ponds across several days, weeks, and months, viral metagenomes revealed that the genetic composition of viral communities was coherent at a broad level, but some individual viral genes experienced rapid changes in relative abundance.

Scaling up From Fragmented Genes to Complete Genomes

While the analyses outlined above were foundational for our current understanding of virus diversity, they were limited by the short length of next-generation sequencing reads which fragmented the view of viral genomes. These limitations were progressively

Box 1 Use of complementary methods to target different types of viruses

A number of approaches have been developed to specifically select and survey the genetic material contained by virus particles in a given sample. Alternatively, viral genomes can also be analyzed from “bulk” metagenomes which include both virus particles and microbial cells. Virus sequences obtained from “bulk” metagenomes will typically reflect viruses infecting their host cell at the time of sampling, either actively replicating or not, while viromes enables a deeper and more focused exploration of the virus diversity in a specific site or sample.

Regardless of the type of sample, viromes are most often generated through a combination of centrifugation, filtration and DNase/RNase treatment, aiming at removing as much of the cellular genomes as possible (Fig. 1). A typical protocol will notably include a filtration through 0.22, 0.45, or 0.8 µm membrane filters to remove bacteria and larger cells. Depending on the initial concentration of virus particles, a concentration step using e.g., iron chloride (FeCl₃), PolyEthyleneGlycol (PEG), or tangential flow filtration step(s), may be necessary to obtain enough material for sequencing library preparation. Cesium chloride density gradients ultracentrifugation can also be used to further separate viruses from extracellular DNA and large particles in complex samples, although this step can also lead to a substantial loss of viral material. Finally, the virus particles obtained are typically treated with DNase or RNase to remove free DNA and/or RNA. Depending on the type of virus studied, the corresponding protocols for RNA or DNA extraction and sequencing library preparation are then applied, after releasing the genetic material from the virus particle through e.g., a heat shock if necessary.

A critical step in this process is to recover enough material for sequencing. While micrograms of DNA were initially needed, several protocols are now available which only require ~ 1 ng of DNA. In addition, a DNA/RNA random amplification step, called “whole genome amplification”, can also be conducted in order to gather enough input material. This type of approach was initially used in almost every virome study, and revealed important information for example on the unsuspected diversity of ssDNA genome viruses in the environment (see below). However, the whole genome amplification process is inherently biased, and these datasets are not quantitative, i.e., one cannot draw any conclusion about the relative abundance of the viruses identified in these amplified metagenomes. Thus, whole genome amplification methods have now been often replaced by advanced library preparation protocols which require nanogram-scale input but enable quantitative datasets well suited for ecological studies. Alternatively, for cases in which target viruses represent a minor part of the templates, targeted sequence capture approaches have been used, mainly in a clinical framework as they can only be applied to viruses with known genomes but can detect these viruses with a very high sensitivity.

The recovery of virus genomes from bulk metagenomes and from viromes each have their own limitations. For bulk metagenomes, viruses typically represent only a minor fraction of all sequences compared to cellular genomes. This means that the virus genomes obtained this way will tend to be restricted to abundant viruses found in their host cells, while viruses that are not infecting at the time of sampling, viruses with a low frequency of infected hosts, or viruses infecting rare hosts will likely be missed. Viromes provide a deeper description of the virus community, since most of the sequencing data will be obtained from virus genomes. In addition, virus particles will not represent only current infections but a more integrated sampling of all recent successful infections, the timing of which depending on the type of sample and the individual virus decay rate. Yet viromes still suffer from several biases. Notably, the size-based selection of virus particles excludes most of the larger viruses such as the “giant viruses”, and viromes also tend to be dominated by viruses with high burst size while under-sampling viruses with low burst size and long infection time. All metagenomes (bulk and viromes) will struggle with very rare viruses, as well as hypervariable viruses which genome will not assemble well. Hence complementary approaches such as targeted capture approach for the former, and long read sequencing for the latter, are being developed (Fig. 1).

Overall, the different methods developed over the last decade to sequence genomes from uncultivated viruses are mostly complementary and can be individually tailored for specific applications. Virus discovery can be achieved through bulk metagenomes or viromes, while viral ecology studies will tend to rely more on viromes as a reflection of virus activity and transport, and metagenomics used as a diagnostic tool in the clinic would be the most likely to use sequence capture. Nevertheless, all these complementary approaches will be needed for achieving a comprehensive picture of viral diversity.

overcome through an increase in sequencing throughput associated with improvements in sequence assembly and analysis tools. The first large-scale assemblies of viral genomes from short metagenomic fragments were published around 2010, and quickly became a standard analysis in the viral metagenomic field so that by the year ~ 2015, complete or near-complete virus genomes were routinely reported and analyzed in viromics studies.

In only a couple of years, metagenomics has thus transformed the way scientists can identify and study viruses in the environment, as illustrated by the quick rise of virus genomes and genome fragments assembled from metagenomes available in public databases (Fig. 2). In 2010, only 84 viral genomes (fragments) assembled from metagenomes were publicly available, while this number reached 35,000 in 2016, and 775,000 in 2018. Genome sequences of uncultivated viruses are frequently obtained not only from viral metagenomes, i.e., metagenomes from virus-targeted samples, but also from “bulk” metagenomes in which virus particle were not enriched and viral and microbial sequences are mixed. Combined with genome sequences obtained from isolates, these “uncultivated virus genomes” represent the foundation of an extensive mapping of the viral sequence space.

Viral Metagenomics in the Clinic

Over the past few decades, a number of molecular techniques, such as (q)PCR or ELISA, have been developed and used to detect pathogenic viruses in clinical samples. However, these techniques can only detect previously known viruses, and often require

Fig. 1 Overview of the viral metagenomics workflow. The overall process used to generate and analyze viral metagenomes can be divided into four major steps: (i) Collection of environmental and/or clinical sample, (ii) sample preparation, (iii) library preparation, and (iv) sequence analysis. The sample preparation step can target either the cellular fraction (left) or the viral fraction (right) in which case viral particles are often further concentrated and purified to remove free nucleic acids. *Targeted sequence capture can be applied to the extracted DNA/RNA to enrich for a specific virus. **While whole genome amplification was initially used routinely for viral metagenomes, it has now been supplanted by methods enabling the preparation of more quantitative libraries from low input (~ 1 ng), hence whole genome amplification is now primarily used in single-cell or single-virus-particle experiments. ***The genome assembly can be bypassed if using long-read sequencing technologies, although these long-read datasets require a more careful error correction. ****Genome binning, i.e., the identification of multiple contigs assembled from a metagenome and corresponding to the same genome, is typically only used for large genomes (e.g., > 500 kb), and individual contigs are directly analyzed instead for most viruses.

specific assays for each pathogen. Metagenomics instead offers the possibility to detect known and novel viruses without prior knowledge from a single analysis, and is thus well suited and already applied to study emerging and/or rare viruses, as well as cases which remain negative using the available diagnostic tests (see below). A number of challenges remain however for viral metagenomics to become a standard clinical procedure. First, given the current cost associated with sample processing and sequencing, metagenomes are still more expensive and slower than ELISA's or qPCR assays. Second, there is no generally validated bioinformatics pipelines than can perform a rapid, sensitive, and specific analysis of the obtained data on a bench top computer. Finally, physicians will have to be trained and guided to deal with the obtained breadth of data. Specifically, it is becoming clear that each individual is chronically infected with a dozen or more eukaryotic viruses (many of which have not been associated with any disease, e.g., anelloviruses), and that many known viral pathogens can also cause asymptomatic infections. Therefore, a physician might get a list of viruses (and other potentially pathogenic or unknown organisms), and it will be a challenge to identify the actual cause of a particular disease. Nevertheless, the price of sample preparation and high throughput sequencing has declined enormously in the last decade including with the development of smaller and faster machines, while automatic virome

Fig. 2 Size of virus genome databases over time, host linkage information, and examples of uncultivated virus genomes. A. The total number of genomes from isolates was based on queries to the NCBI nucleotide database portal, while the number of uncultivated virus genomes was estimated by compiling data from the literature and from the IMG/VR database. The number of sequences is displayed on a log₁₀ scale. B. Comparison of 3 complete viral genomes assembled from viral metagenomes sampled from the Indian, Pacific, and Atlantic oceans, through the *Tara* Oceans expedition. These sequences were identified and analyzed as part of the “Global Ocean Virome” dataset (GOV). Predicted genes are colored by functional annotation. C. Overview of the host predictions available for uncultivated virus genomes in the IMG/VR database. Host prediction was based on signals including sequence similarity with isolate viruses, prophages, and CRISPR spacers derived from known bacterial and archaeal genomes.

analysis pipelines are being actively developed, so that metagenomics will likely be available in the near future as a routine test allowing physicians to get a viral diagnosis from a biological sample in a matter of minutes to hours in their home office or on the clinic bedside.

Metagenomic Discovery of New Viral Pathogens

Currently, metagenomics is most often used in a diagnostic context when both conventional and enhanced molecular testing fail to identify a causative agent in a sample. These cases can represent a significant fraction of patients for diseases such as acute diarrhea, for which an etiological agent is identified in only ~ 60% of cases. In this framework, metagenomic analysis can lead to the discovery of unexpected or novel viruses that are associated with a specific set of symptoms.

First, metagenomics can successfully identify known viruses in unexpected sample types. These studies include the detection of enterovirus D68 in clinical samples (rectal, throat, and oral swabs as well as blood samples) in cases of acute flaccid paralysis, the detection of herpes simplex virus 1 (HSV-1) in cerebrospinal fluid samples of a patient with encephalitis, and the detection of mumps vaccine virus from the brain biopsy of a patient with chronic encephalitis. In addition, new human pathogens only distantly related to known viruses have also been discovered with metagenomics. These include the Bas-Congo virus, a rhabdovirus that was associated with a 2009 hemorrhagic fever outbreak in the African Congo, as well as novel rhinovirus, bocavirus, arenavirus, and parechoviruses. Finally, entirely novel types of potentially pathogenic viruses have been described through metagenomics, including previously unknown cycloviruses, cosaviruses, and klasseviruses.

Diagnostics through viral metagenomics has also been applied to non-human animals as well as plants, and similarly revealed new potential viral pathogens in organisms showing unexplained symptoms. Multiple new virus types including novel parvoviruses, polyomaviruses, sapoviruses, and picomaviruses were for example identified in livestock samples (porcine and bovine), while a large diversity of persistent RNA viruses were newly identified across several groups of plants. However, it is important to note that the detection of a (novel) virus in a sample from a patient with an illness of unknown etiology does not prove causation, even in cases of a demonstrated significant association between the presence of the virus sequence and the observed symptoms. Hence, metagenomics will often be the first step of a longer process involving attempts to propagate the virus in culture, or monitoring healthy individuals exposed to the suspected pathogen (see below “Future of viral metagenomics: major challenges and upcoming innovations”).

Epidemiological Surveillance and Environmental Monitoring

In parallel to the diagnosis application, metagenomics is also very well suited for environmental surveillance. Species representing important reservoirs of viruses with high zoonotic pandemic potential such as mosquitoes, rodents, and bats have been specifically targeted in this context. A recent study investigating the virome of more than 200 invertebrate species (a fraction of known invertebrate species), identified more than 1,400 novel RNA viruses, exemplifying that the diversity of unknown eukaryotic viruses

in the environment is enormous and only poorly characterized. Since the majority of human pandemics have a zoonotic origin, one hope is that such metagenomic surveillance will allow a faster identification of novel pandemic viruses during outbreaks, as well as identify their natural reservoirs. This knowledge is crucial for an appropriate and fast response from a medical and global health perspective. As an example, in the last two decades zoonotic coronaviruses were able to jump from bats to humans and pigs. Both the SARS (Severe Acute Respiratory Syndrome virus) and MERS (Middle East Respiratory Syndrome) viruses caused large-scale disease outbreaks in humans, whereas SADS (Swine Acute Diarrhea Syndrome) caused an epidemic in the swine industry. Ongoing efforts to characterize the virome of such reservoir animals will facilitate the implementation of control measure to prevent epidemics or enforce appropriate actions to stop ongoing epidemics. In an ideal situation, obtained environmental virome data in combination with biochemical experiments could help with the early identification of candidate viruses with the potential to transfer to a human host. For instance, a combination of metagenomics and DNA synthesis-based experiments revealed that a novel coronavirus (WIV1-CoV) initially detected in bat samples could be prime for transfer and emergence into human hosts.

Metagenomic analysis can also be leveraged in response to viral outbreaks, for example to rapidly determine viral subtypes in a novel infection source. This has been applied to cases of influenza infections as well as for a novel wild type Ebola virus outbreak, for which metagenomic approaches could correctly identify the causative agent, even in cases where traditional methods were unsuccessful because the wild type virus was too distantly related to known Ebola viruses. A correct and rapid identification of these viruses could enable the application of the correct therapeutics and guide preventive efforts against potential epidemics.

Characterizing the Global Viral Diversity

While viruses of humans, animals, and plants may have direct clinical or economic relevance, the vast majority of the (estimated) 10^{31} virus particles on Earth infect micro-organisms, including bacteria, archaea, protists, fungi, and other environmental microbes. Initial studies of environmental viral diversity focused on human feces, coastal and open ocean, freshwater lakes, as well as hypersaline and hot geothermal ponds, because protocols for efficient separation of virus particles from microbial cells were first developed for aquatic samples. Importantly though, recent innovations and technology improvements now enable application of viromics to more complex samples such as soil, groundwater, or ice cores, helping to expand our view of global viral diversity both in the human microbiome and in the environment.

Identifying Globally Dominant Bacteriophages

A striking example of a viromics discovery is that of a highly abundant bacteriophage, named “crAssphage”, that was assembled from a set of human fecal viromes in 2014. The crAssphage genome was identified by combining information from 12 individual viromes, which yielded a high-confidence 97 kb sequence with matching 5' and 3' ends, suggesting that it represented a complete circular genome. This crAssphage genome was mostly unrelated to any isolated phage genome known at the time: from the 80 predicted proteins, less than half (39) were even remotely similar to known proteins or domains, and only 25 had a predicted function, such as “phage structural protein” or “DNA helicase”. While clearly novel, crAssphage was also found to be uniquely abundant and ubiquitous: its genome was detected across 940 metagenomes, primarily from human feces, at average levels that were six times higher than all other known phages combined. By applying several independent computational host-prediction approaches, a bacterial host (*Bacteroides*) was predicted. Thus, in this instance, metagenomics revealed what remains to date the most abundant and widespread phage associated with the human gut microbiome, which had until then evaded detection through classical approaches like laboratory cultivation and PCR.

Assembling genomes of uncultivated viruses can not only identify some of the most abundant and widespread viruses in an ecosystem, but these sequences also represent foundational data for targeted follow-up experiments aimed at further characterizing these novel viruses. In the case of crAssphage, two major studies leveraged this initial genome sequence to better understand the diversity and host of these phages. First, predicted proteins from the original crAssphage genome were used as “bait” to identify related phages in a broad range of metagenomes. This revealed an extensive and diverse group of “crAss-like” phages predicted to represent a new family within the *Caudovirales* order, that may be related to *Podoviridae*. Genome comparisons within this new family also enabled the identification of conserved structural and replication gene modules. Meanwhile, another study was able to isolate a member of the crAssphage-like family through broth enrichment on *Bacteroides intestinalis* strains isolated from human gut samples, confirming the computational predictions from bioinformatic analyses that these phages were likely infecting *Bacteroidetes* hosts and had a *Podoviridae*-like morphology.

In 2016, a comprehensive effort to chart viral diversity across the global oceans yielded a similar observation. This study detected more than 15,000 viral genome fragments, and grouped them into clusters of closely related viruses, approximately consistent with genera in the viral taxonomy. Two out of the four most highly abundant and ubiquitous clusters were entirely novel and had not been described before, while the other two were similar to known bacteriophages. With viral metagenomics being applied to a larger set of samples and environments, and with bioinformatic analyses including genome assembly and interpretation constantly improving, novel groups of dominant and widespread viruses may thus be progressively revealed across many environments.

Unveiling New Uncultivated Giant Viruses

Another group of viruses whose known diversity has been vastly expanded through metagenomics are the so-called “giant viruses”, dsDNA viruses with a uniquely large virion ($\sim 0.5\text{--}1\ \mu\text{m}$) and genome (often $> 1\ \text{Mb}$), blurring the boundaries between “simple” viruses and “complex” cellular life. Following the isolation and characterization of the first giant virus in 2004 (“*Acanthamoeba polyphaga* mimivirus”), around 50 other members of this group have been isolated, the vast majority by using an *Acanthamoeba* host. However, metagenome analyses suggest that the true diversity of giant viruses vastly exceeds the number of isolates.

As early as 2013, an analysis of 17 metagenomes revealed that giant viruses could be found in the ocean at concentrations of $\sim 10^4$ genomes/ml. These initial studies were based on the detection of marker genes, since the technologies available at the time did not enable the assembly of complex and large genomes like those of giant viruses. More recently, four complete or near-complete giant virus genomes could be assembled from metagenomes of a wastewater treatment plant. This revealed a new subgroup of giant viruses named Klosneuviruses which comprised some genomes with the largest set of translation system components found at the time in any virus, including aminoacyl transfer RNA synthetases with specificity for all 20 amino acids. Undoubtedly, as our collective ability to assemble large genomes from metagenomes increases, the giant virus diversity will keep expanding.

Revealing the Extraordinary Diversity of ssDNA and RNA Viruses

While most sequencing technologies are designed for dsDNA templates (see [Box 1](#)), our knowledge of single-stranded DNA (ssDNA) and RNA viruses has also been transformed by metagenomics. In both cases, specific sample processing steps are required to access these genomes, however their relatively short length (usually $< 20\ \text{kb}$) means that complete genomes are routinely assembled from total community shotgun metagenomes that target all the nucleic acids in an environment. As for dsDNA viruses, metagenomics revealed that these ssDNA and RNA viruses were much more diverse and broadly distributed than previously inferred from isolation and cultivation approaches.

Enrichment for circular ssDNA viruses can be achieved through phi29-based whole genome amplification, which is known to over-amplify small circular ssDNA templates. Pragmatically, this translates into viral metagenomes that are dominated by ssDNA viruses with circular genomes, which helped shed a new light on the diversity of two major groups: bacteriophages from the *Microviridae* family, and eukaryotic viruses from the CRESS DNA (Circular REp-encoding ssDNA) supergroup. The latter saw the more striking expansion: until 2009, these viruses were known exclusively in plants and vertebrates, specifically pigs and birds, yet in less than a decade, CRESS DNA viruses were detected in metagenomes sampled from primates, arthropods, and unicellular protists, as well as diverse aquatic, terrestrial, and man-made ecosystems. Hence, while the exact host range and impact of these viruses remain to be fully characterized, metagenomics already revealed that ssDNA viruses are ubiquitous and can be found associated with all types of cellular hosts.

For RNA viruses, several additional sample processing steps have to be performed to preferentially sequence viral RNA, typically including reverse transcription and random amplification. The most comprehensive study of RNA virus diversity to date included samples from > 220 invertebrate species across 9 phyla, and led to the discovery of nearly 1,500 novel viruses across the 13 major clades of RNA viruses. In addition, the assembly of complete genomes provided new insights on the recombination patterns of these viruses, highlighting a remarkable propensity of RNA viruses to exchange or acquire genes horizontally, both with other viruses and with their host. RNA viruses were also detected in a much broader host range than currently known from isolates, although these host associations now have to be confirmed through laboratory experiments since virus detection in metagenomes does not equate active infection.

Leveraging Time Series to Track Virus Populations Dynamics

Improvements in metagenomics protocols post ~ 2015 enabled the analysis of dozens of samples in parallel. In the field of viral metagenomics, this increased capacity has been leveraged specifically to analyze viral signal along time series and thus investigate virus-host dynamics in nature. Such datasets have notably been obtained from freshwater lakes, for which recurrent sampling across months or years can be done, and which usually harbor a high concentration of viruses. These first explorations of environmental viral diversity across months and seasons indicated that viruses display a large range of relative abundance patterns, from “ephemeral” ones with a single peak in abundance to “constitutive” ones detected in virtually all samples. Some of these patterns were seasonal and possibly linked to similar patterns of abundance for their microbial hosts, while other viruses displayed drastic changes from one year to the next. For instance, although longitudinal virome studies of the human gut are scarce, available data suggests a rather stable population of gut viruses (almost exclusively phages) in adults over time, whereas the infant gut virome is much more variable and may be dominated by eukaryotic viruses at particular time point coinciding with an acute enteric infection.

Time series metagenomes are especially interesting to discover and predict virus-host associations, and to analyze dynamics of known virus-host pairs. The former approach already provided host prediction for several giant viruses that are so far known exclusively from metagenome assemblies, and suggested that these may be linked to uncultivated protist hosts. The latter raised the intriguing possibility of complex and diverse virus-host relationships occurring in nature: while the expected patterns would be a strong correlation between virus and host abundances with possibly a short lag in the virus signal in a typical predator-prey

fashion, these large-scale metagenome time series instead suggested that some of the viruses could peak prior to a peak in abundance of their host, while other virus-host pairs showed no similarity in relative abundance at all. These conflicting results likely reflect the complex interactions at play between viruses and microbes in nature, including variable host ranges, from viruses infecting a unique host strain to others infecting multiple host species sometimes across different genera, as well as the spectrum of infection dynamics from fast-acting lytic viruses to slower, temperate, and even chronic ones, and the development of resistance to the virus among the host population. Despite these numerous challenges in their analysis, time series metagenomes are poised to become a key approach to complement laboratory experiments and untangle the intricate relationships between viruses and their hosts.

Future of Viral Metagenomics: Major Challenges and Upcoming Innovations

Metagenomics has quickly become a major tool for exploring viral diversity, yet several challenges need to be addressed in order to fully leverage the potential of these methods. First, metagenomes built from limited input material are still difficult to reliably obtain and interpret, and do not yet provide a comprehensive and quantitative view of the viral community present in the sample. This includes environments with low biomass such as some human tissues, hydrothermal vents, ice cores, or ancient samples, but also samples with a thick substrate or matrix to which cells and virus particles tend to adhere such as human lung mucus or coral samples. Improvement in the recovery of cells and virions from this type of substrates and in the generation of quantitative libraries from sub-nanogram input will help better survey these viral communities.

The second major challenge lies in the absence of direct host information for genomes assembled from metagenomes. In a clinical context, this means that one of Koch's postulates, which requires that the candidate etiological agent be isolated from a diseased organism and grown in pure culture, cannot be fulfilled. Already, several smacoviruses which had been detected in human samples metagenomes and suspected to represent new human viral pathogens have been found to likely infect prokaryotic cells from the human microbiome instead. In a similar way, evidence is emerging that picobirnaviruses, which are believed to be eukaryotic viruses, might actually infect bacterial cells. These examples should thus serve as a cautionary tale when trying to detect entirely new viral pathogens from mixed samples containing both human and microbial cells. A modified Koch's postulate for the metagenomic era has been proposed in which potential new pathogens must first be present and more abundant in the diseased subject compared to matched control. Then, experiments using either a sample from a disease subject or an artificial virus obtained through DNA synthesis and expression in cell cultures must be performed to demonstrate that this agent induces disease in another healthy subject. While not trivial, these additional experiments based on metagenomic results could still lead to the identification of viral pathogens much more quickly than classic culture techniques.

In an ecological context, associating uncultivated viruses to their host is also critical to understand their impact on microbial communities and to meaningfully integrate viruses into ecosystem models. Because viral ecology studies typically include hundreds to thousands of viruses of interest, these host associations are typically derived from *in silico* approaches based on various types of genome sequence comparison. While methods for *in vitro* confirmation of these metagenome-derived virus-host pairs are currently being developed, they will need to improve both in terms of scale and resolution to provide meaningful host association for the vast diversity of uncultivated viruses.

Among the expected technological improvements, two stand out as likely to benefit the field of viral metagenomics in the near future. First, long-read sequencing technologies are progressively amenable to the sequencing of environmental viral communities. Pragmatically, this means that instead of having to assemble virus genomes from short reads, a process which can yield potentially erroneous and/or incomplete genome sequences, a complete viral genome could be sequenced as a single read. Once broadly available, these long-reads metagenomes will not only bypass assembly issues but also provide valuable information about virus genome evolution by enabling whole-genome phasing of polymorphisms. Meanwhile, in an epidemiological context, long-read sequencing technologies associated with miniaturized devices, streamlined sample preparation, and live scanning of the sequencing results offers unique possibility for real-time surveillance or diagnostics. This is especially the case for the MinION sequencer based on Nanopore sequencing technology, allowing the identification of viral pathogens from a patient sample in less than 6 h, compared to more than 20 h for other sequencing technologies. The computational framework to analyze and share these types of data in a timely, safe, and meaningful way remains to be built, however it is likely that metagenomics through portable genome sequencers will become a major component of the epidemiological toolkit in the near future.

Complementarily, the throughput of sample preparation protocols and short-read sequencing approaches is likely to keep increasing at a fast pace. Concretely, these technological improvements will translate into a lower cost per sample, and an increased ability to process hundreds of samples in parallel in a timely fashion, in particular through laboratory robotics automation. For the detection of viral pathogens as well as the exploration of viral diversity and virus-host interactions in nature, this increased throughput will provide the opportunity to generate e.g., high-resolution time-series, possibly including paired cellular and viral size fractions with multiple replicates per sample, enabling more robust and sensitive data analyses.

Eventually, a fully developed virus metagenomics toolkit will enable the accurate identification of viruses in natural, clinical, and biotechnological samples for monitoring and diagnostics purposes. Moreover, as bioinformatics analysis tools advance, the reconstruction of full viral genome sequences will allow predictions to be made for the most important viruses in different environments, leading to the reconstruction of environmental virus-host networks and, when combined with other 'omics' approaches, the comprehensive evaluation of viral activity across an entire ecosystem. Collectively, these studies should lead to a

deeper understanding of viral impacts on ecological, evolutionary, and metabolic processes as well as information on potentially new viral pathogens and putative molecular virus-host interactions which could then be further characterized through targeted laboratory experiments. Hence viral metagenomics will remain a central and fundamental way to interrogate the viral world in many research fields.

This is an update of K. McLeod, C. Upon, Virus Databases, In Reference Module in Biomedical Sciences, Elsevier Inc., 2017, doi:10.1016/B978-0-12-801238-3.95728-3.

Significance of Viral Databases

Viral disease outbreaks are an ongoing threat to public health. Every few years, viral pathogens, including various influenza strains, SARS and MERS coronaviruses, Ebola, and most recently Zika virus, have caused considerable personal and economic loss (see “Relevant Websites section”). Identification of causative agents, clinical reporting of infections, and epidemiological surveillance are all critical during these outbreaks. Such efforts to identify the causes of these infectious outbreaks lead to a wealth of information about the viruses and their host. Databases allow storage and analysis of this information to fuel further wet-lab experimentation on the causative agents and comparative analyses of their genomes. Such research efforts are important for predicting, preventing and limiting future outbreaks.

Comprehensive databases such as Viral Pathogen Resource (ViPR, see “Relevant Websites section”) and Influenza Research Database (IRD, see “Relevant Websites section”) have been instrumental in providing a one-stop-shop for data and analytical tools for basic and applied research in virology. The significance of such databases is evident in multiple use cases that demonstrate the utility of the resources. For example, data and bioinformatics tools from ViPR and IRD have facilitated research into detection and diagnostics of viral pathogens, prediction of viral hosts and environmental reservoirs, viral evolution, development of vaccines, discovery of genomic determinants of virulence, and anti-viral drug development. Importantly, these resources allow investigators at all levels of training and expertise to easily perform their desired analyses and to contribute critical information about infectious disease outbreaks.

Overview of Viral Databases and Analytical Tools

Viruses infect all kingdoms of life. In this article, we focus on database resources for viruses that infect humans and other animals. We call attention to databases such as Plant Viruses Online (see “Relevant Websites section”) and the Prokaryotic Virus Ortholog Groups (pVOGs) (see “Relevant Websites section”) for readers interested in viruses that infect other host organisms, which are out of scope of this article. The landscape of databases and analytical tools available for human virology research is guided by research and development goals for priority pathogens. The available resources can be categorized as databases that store specific data types and bioinformatics webtools that offer specific analytical capabilities. These two essential functions have also been combined and integrated in comprehensive resources such as ViPR and IRD.

Types of Databases

Several types of databases are available for virology research that can be distinguished based on the type of data they contain or the pathogen area of focus (Table 1). For instance, many popular databases focus on storing information about specific biomolecules, such as gene and protein sequences, immune epitopes, or protein structures. These databases can be further distinguished as sequence archives such as GenBank (see “Relevant Websites section”), and UniProt (see “Relevant Websites section”), where data is deposited by the primary investigators and curated DBs such as RefSeq (see “Relevant Websites section”) that integrate additional knowledge (e.g., annotations) with sequence records to provide an enhanced knowledgebase. Biomolecule information other than sequences is also stored in other databases, including the Protein Data Bank (PDB; see “Relevant Websites section”), which stores 3D structural data, the Immune Epitope Database (IEDB; see “Relevant Websites section”), which catalogs experimental data on B cell and T cell epitopes studied in humans and other animals and the Virus Particle Explorer (VIPERdb; see “Relevant Websites section”), which stores the structures of viruses with icosahedral virions.

Virology databases have also been designed to focus on particular taxa of viral pathogens. For example, recognizing hepatitis B virus as a major public health problem worldwide, the Hepatitis B Virus Database (HBVDb; see “Relevant Websites section”) has been designed to facilitate research on the genetic variability of HBV and its resistance to treatment. HBVDb allows the analysis of annotated sequences for genotyping and drug resistance profiling. Similarly, a collection of databases for research on the Human Immunodeficiency Virus (HIV) are available (see “Relevant Websites section”) that contain comprehensive data on genome and protein sequences and immunological epitopes. Because influenza virus poses perhaps the most persistent major global public health threat, several databases are dedicated to research on influenza. For instance, the Global Initiative on Sharing All Influenza Data (GISAID; see “Relevant Websites section”) is an access-controlled resource of influenza sequence information and related epidemiological data. FluNet (See Relevant Websites section) is a global web-based influenza surveillance data collection, maintained at the World Health Organization (WHO) and available for tracking the movement of flu viruses globally. The Influenza Virus Resource (see “Relevant Websites section”) supports the search and analysis of

Table 1 List of databases and webtools

Category	Name	Types of data/services	Weblink
Databases	GenBank	Gene and genome sequences	https://www.ncbi.nlm.nih.gov/genbank/

	VirusDetect	viral detection from small RNA datasets using both <i>de novo</i> and reference-based assemblies	http://virusdetect.feilab.net/cgi-bin/virusdetect/index.cgi
	Viral Genome ORF Reader (VIGOR)	Homology-driven viral gene prediction and genome annotation	https://github.com/JCVenterInstitute/VIGOR4
	STRING-Viruses	Assessment of viral-host protein-protein interactions using visualization tools such as Cytoscape	http://viruses.string-db.org
	NextStrain	Rapid, real-time tracking and prediction of spatio-temporal spread of infection during infectious outbreaks	https://nextstrain.org

influenza genomic and protein sequences at National Center for Biotechnology Information (NCBI). The Influenza Research Database (IRD; see “Relevant Websites section”) provides the most comprehensive collection of influenza virus-related data and an integrated suite of analytical and visualization capabilities for research on influenza virus.

In contrast to the aforementioned resources that are focused on a particular data type or virus, the ViPR resource (see “Relevant Websites section”) is unique in that it provides cross-referenced data of multiple types on all high priority human pathogenic viruses that pose a threat to public health, except HIV. Each virus family has a dedicated portal within ViPR that offers intuitive, customized search interfaces and analytical options tailored for each of the virus families. ViralZone (see “Relevant Websites section”) provides access to a highly curated and extensive knowledgebase about a wide range of viruses.

Types of Bioinformatics Webtools

Research in virology is heavily dependent on data mining using sophisticated bioinformatics tools. With the foresight into the importance of such capabilities, several dedicated webtools are available for the users to conduct various types of analyses on viral genomes. For instance, tools such as IDSeq (see “Relevant Websites section”), Virome (see “Relevant Websites section”) and VirusDetect (see “Relevant Websites section”) allow detection of viruses from deep-sequencing of metagenomics samples. IDSeq is designed with the aim of real-time pathogen detection from metagenomes. Virome focuses on environmental metagenomes, whereas VirusDetect specifically uses small RNA datasets to detect viruses using both *de novo* and reference-based assemblies.

Once a novel virus isolate or variant is detected, tools such as the Viral Genome ORF Reader (VIGOR; see “Relevant Websites section”) enable genome annotation. VIGOR is a homology-driven viral gene prediction program that yields predicted proteins and mature peptides for newly sequenced isolates and variants of human virus. The software uses a set of highly curated databases enabling VIGOR to annotate a given viral genome. Currently VIGOR supports gene prediction and annotation of about 25 different virus taxonomic groups.

Tools are also available to study the viral pathogen in the context of its host environment. For instance, STRING-Viruses (see “Relevant Websites section”) is a webtool available as part of the STRING database that allows assessment of protein-protein interactions using visualization tools such as Cytoscape. This webtool is particularly important for studying how viral proteins interact with host proteins during various stages of infection. Likewise, NextStrain (see “Relevant Websites section”) is a webtool that enables rapid, real-time tracking of evolving pathogen populations during infectious outbreaks. NextStrain is an open source system that tracks mutation marker data on pathogen phylogenies to make inferences about epidemiologically-relevant parameters such as spatio-temporal spread of the infection within a host population.

Virus Pathogen Database and Analysis Resource (ViPR) and Influenza Research Database (IRD)

For the remainder of this article, we focus on describing two related database and analytical resources available for research on human viral pathogens – ViPR and IRD – as examples for how these types of resources are developed and used. For a more comprehensive list of other available virus database and analysis resources, we encourage the reader to explore additional information about resources listed at ViralZone (see “Relevant Websites section”).

The National Institute of Allergy and Infectious Diseases (NIAID) at the U.S. National Institutes of Health (NIH) implemented the Bioinformatics Resource Centers (BRCs) for Infectious Diseases program to support research on priority pathogens of humans. As a result, the BRC focused on viral pathogens has developed the ViPR and IRD resources as publicly-accessible online repositories for viruses that adversely affect public health with the aim of integrating research and surveillance data. ViPR (see “Relevant Websites section”) is unique amongst viral-centered databases in offering a wealth of information on a large number of viral families. In contrast, IRD (see “Relevant Websites section”) is a parallel resource that is focused exclusively on Influenza virus. The objective of both resources is to provide virus data and analytical capabilities to advance the understanding of virus transmission, pathogenesis, and host range, and to support the development of diagnostics and therapeutic interventions.

Sources of Data

The ViPR and IRD databases integrate data from three sources ([Table 2](#)):

Data Aggregated From Public Data Archives

The ViPR and IRD databases capture various data types from multiple publicly-accessible data archives. ViPR and IRD integrate genomic sequence information from GenBank (see “Relevant Websites section”), protein sequences from UniProt (see “Relevant Websites section”), protein structures from the Protein Data Bank (PDB; see “Relevant Websites section”), experimentally determined T-cell and B-cell epitopes from the Immune Epitope Database (IEDB; see “Relevant Websites section”), and Gene Ontology annotations from the GO database (GO, see “Relevant Websites section”). All data types are regularly updated and are searchable using their original accession numbers within intuitive web-based user interfaces.

Direct Submission of Novel Data

In some cases, active research projects supported by the U.S. National Institutes of Health and other interested parties submit data and related metadata directly to ViPR and IRD. For instance, NIAID-funded Systems Biology Consortium for Infectious Diseases research programs submit a variety of different transcriptomic, proteomic, and metabolomic datasets that investigate in vivo and in vitro host responses to viral infections. The Genomic Sequencing Centers for Infectious Diseases (GCID) program submit detailed structured metadata, including clinical information such as disease symptoms, severity, and diagnostic test outcomes, that are linked with sequence records of the corresponding virus isolate obtained from GenBank. IRD serves as the repository for the influenza human and animal surveillance data collected by the Centers of Excellence for Influenza Research and Surveillance (CEIRS) program.

Derived and Predictive Data

The IRD and ViPR development team generates and integrates unique derived data from bioinformatics analysis pipelines performed in-house, tailored specifically for a given taxonomic groups. Derived data include improved and consistent metadata annotations including strain name, clade and genotype information, virus taxonomy, host and country of isolation, and collection date. For instance, the ViPR annotation process extends information available in the representative RefSeq strain for each species. The process uses multiple sequence alignment to map homologous regions across related viral genomes to map mature peptide cleavage sites on

Table 2 Sources of IRD and ViPR data

	<i>Data source/algorithm</i>	<i>Data type</i>	<i>Component</i>
<i>Imported public data</i>	NCBI - GenBank	Genome sequences/annotations	ViPR and IRD
	NCBI - RefSeq	Genome sequences/annotations	ViPR and IRD
	Immune Epitope Database (IEDB)	Curated epitopes	ViPR and IRD
	UniProt	Protein annotations	ViPR and IRD
	RCSB Protein Data Bank (PDB)	Protein 3D structures	ViPR and IRD
	Catalytic site atlas	Active sites	ViPR and IRD
	PATRIC & VBRC Bioinformatics Resource Centers	Orthologs	ViPR
	AVIBase	Bird taxonomy	IRD
<i>Data submitted directly</i>	NIAID Genome Sequencing Centers	Clinical metadata	ViPR and IRD
	NIAID Systems Biology program	Host factor data	ViPR and IRD
	ViPR-funded driving biological projects	Host factor data	ViPR
	NIAID Centers of Excellence for Influenza Research and Surveillance (CEIRS)	Surveillance records,	IRD
	NIAID Centers of Excellence for Influenza Research and Surveillance (CEIRS)	Serology test records	IRD
<i>ViPR/IRD generated data</i>	NCBI BlastP	Sequence similarities	ViPR and IRD
	InterProScan	Domains/motifs	ViPR and IRD
	NetCTL	Predicted CTL epitopes	ViPR and IRD
	ViPR pipeline	Mature peptides	ViPR
	ViPR custom algorithm	Isoelectric point and molecular weight	ViPR
	ViPR curation	Sequence feature variant types	ViPR
	IRD pipeline	SNP/consensus sequence	IRD
	IRD custom algorithm	Isoelectric point and molecular weight	IRD
	IRD curation	Sequence feature variant types	IRD
	IRD curation	PCR primers & probes	IRD
	IRD algorithm	PA-X protein annotation	IRD
	IRD tool	H5N1 clade classification	IRD
	IRD curation	Flu season assignment	IRD
	IRD tool	2009 pH1N1 sequence classification	IRD

polyproteins. Likewise, a custom annotation pipeline is used in IRD to predict open reading frames and sequences for variants of influenza proteins including PA-X, PA-N155, PA-N182, M42, NS3 and PB1-40. The predicted variant proteins can be retrieved from the Nucleotide and Protein Sequence Search pages. Various tree-based clade classification tools are also available and have been used to predict clades and genotypes of pathogenic strains of several viruses including Zika, rotaA, and Hepatitis C virus in ViPR and H1N1, H5N1 and swine H1 strains in IRD. Furthermore, Sequence Features (SFs) are derived using information integrated from UniProt, GenBank, IEDB and the scientific literature followed by inspection and validation by domain experts. SFs are protein regions with important structural, functional, immune epitopes, or sequence alteration characteristics. Once the SF protein regions are defined, the extent of sequence variation observed in each region is determined as a series of Variant Types (VTs). Lastly, the Host factor component of IRD/ViPR contains a variety of derived data that gives insights about the systems-level infection dynamics. For instance, host factor biosets are group of genes/proteins/metabolites that are significantly differentially expressed/abundant at different times post infection. Data models derived using Weighted Gene Coexpression Network Analysis (WGCNA) are available to aid identification of co-expressed genes that may be functionally related, tightly co-regulated or members of similar pathway. The set of co-expressed genes can also be visualized as Cytoscape networks where nodes represent genes and edges represents the strength of co-expression.

Data Summary

Table 3 ViPR and IRD offer frequent updates on all data types. Genome sequence data are updated daily (IRD) or weekly (ViPR) while all other data types are updated with each bimonthly release. As of September 23, 2019, ViPR provides data on 667,249 virus strains from nearly 6126 viral species belonging to 20 families including *Arenaviridae*, *Caliciviridae*, *Coronaviridae*, *Fimoviridae*, *Filoviridae*, *Flaviviridae*, *Hantaviridae*, *Hepeviridae*, *Herpesviridae*, *Nairoviridae*, *Paramyxoviridae*, *Peribunyaviridae*, *Phasmaviridae*, *Phe-nuoviridae*, *Picornaviridae*, *Poxviridae*, *Reoviridae*, *Rhabdoviridae* and *Togaviridae*. It contains sequences from nearly 883,170 genomes, out of which upwards of 110,742 are complete genome sequences. Sequence data on > 2,100,000 proteins are also available and contains various attributes including annotations, mature peptide data, experimentally determined epitopes, etc. ViPR contains a total of 16,945 3D protein structures from PDB and 61,816 experimentally-determine immune epitopes. **Table 3** displays a breakdown of available data; details may be found at the link (see “Relevant Websites section”).

Table 3 Data summary. Numbers of various data types available in ViPR and IRD as of September 23, 2019 are shown. All data types are regularly updated

Data category	Attribute	ViPR	IRD
Genome information	Species	6,126	
	Genomes/segments	883,170	751,002
	Complete genome segments	110,742	419,482
	Proteins	2,143,646	1,184,929
	Mature peptides	243,538	
	Strains	667,249	161,216
	Strains with predicted genotypes	140,817	
	Strains with predicted segments	28,570	
	Genomes with clinical metadata (NIAID GSCID, manual curation)	3,931	
	Orthology group	9,385	
	Functional annotation	1,242,728	
	PubMed references	350,036	180,692
	Sequence feature	1,659	5,629
Number of proteins with specified annotations	Proteins	2,143,646	1,184,929
	Epitopes from IEDB	61,816	3,885
	PDB Files	16,945	1,748
	Pfam domains	1,699,884	1,104,118
	Other domains/motifs	1,295,044	760,672
	GO IDs biological process	155,156	599,355
	GO IDs molecular function	177,460	575,346
	GO IDs localization	262,063	663,293
	GO IDs		792,355
	EC numbers	33,636	
	Proteins with predicted epitopes*	1,769,976	1,089,613
	BlastP Alignments*	1,914,679	
Number of strains with specified annotation	Strains with predicted pH1N1 classification		69,668
	Strains with predicted H5 clade classification		9,042
Number of segments with specified annotation	Total segment sequences		751,002
	Polymorphism data*		437,685
	PubMed references		180,692
Number of Surveillance Samples	Hosts sampled		1,055,511
	Samples		1,233,703
	Samples tested for flu		1,211,204
	Flu-positive samples		80,040
	Samples with sequence data		9,686
	Samples with serology data		339
	Samples with structured metadata		1,233,703

The IRD holds 751,002 total influenza genome segment sequences, 1748 PDB structures and 1,184,929 proteins with predicted epitopes. Also, the IRD is unique in providing host factor datasets generated from experimental infections of host organism and cell lines with various viral strains. These cover a range of pathogens in the *Orthomyxoviridae* and *Coronaviridae* families. Currently, 66 datasets from four types of “omics” experiments (transcriptomics, proteomics, lipidomics, and metabolomics) are provided. Out of 66 datasets 34 have been analyzed for the WGCNA data models and 25 have the Cytoscape network visualization implemented. IRD is also unique in offering human and animal surveillance data collected by Centers of Excellence for Influenza Research and Surveillance (CEIRS). Additionally, in collaboration with the Global Animal Disease Information System the of Food and Agricultural Organization of United Nations, IRD has established links between sequence records in IRD and disease outbreak event records in EMPRES-I (see “Relevant Websites section”).

KEY DATA FEATURES of ViPR and IRD

- Comprehensive and up-to-date
- Consistent annotations
- Well-curated Influenza variant proteins
- Mature peptides for *Flaviviridae*, *Coronaviridae*, and *Picornaviridae*
- Well-curated metadata about geographic locations, host species, date of isolation, etc.
- Unique data types including host factor, sequence features and animal and human surveillance information

Data Curation

ViPR and IRD offer highly-curated data that has been vetted using computational and manual curation strategies. For instance, an in-house curation and annotation pipeline provides curated sequences from which sequence anomalies have been detected for potential removal during downstream analysis. Along with the sequence data, the ViPR team has manually-curated the scientific literature to provide improved and consistent annotations of metadata including the geographic location, year, and host for many clinically-relevant taxonomic groups. The highly curated strain level data are displayed with a Genome Map image and a Protein Information table from which detailed structural and functional information for a given gene/protein can be obtained. ViPR utilizes RefSeq strains to extend the manually-curated annotations to strains belonging to the same taxon. Furthermore, RefSeq sequences are used to construct virus ortholog groups and their associated annotations, which enable identification of proteins with similar function within a given virus taxon. ViPR and IRD also offer curated data on T-cell and B-cell immune epitopes and their predicted positioning on protein structures from the IEDB. Data curation in ViPR and IRD continues to grow and expand beyond sequence and strain level information. For example, both databases offer curated antiviral drug data from the DrugBank (see “Relevant Websites section”), including the descriptive drug information, 3D structures for target complexes, interaction sites as sequence features and antiviral resistance mutations to aid in assessing the risk of anti-viral drug resistance development.

Data Retrieval

Search Interface

ViPR offers customized search interfaces to allow for the retrieval of selected genomic, structural and other data records using specific metadata for different virus families. Users initiate the search by selecting a virus family on the home page. A user can narrow the search data specific to a virus strain by querying the database using genus or species, geographical location and date of isolation, virus host, and clinical or experimental data. The user also has an option to cast a wider net using keywords with further narrowing using advanced search options. Once a strain or set of strains is selected, detailed genomic and protein sequence information and associated annotation can be accessed. These data can then be directly analyzed using any of the appropriate tools available from within ViPR.

Because IRD is dedicated to influenza viruses, the search interface design is guided by the availability of influenza strain-specific data. Users can query the database using the branching logic inherent in the database. For instance, users can search for complete or partial genome and segment sequences, and proteins by directly entering the name of the strain(s) of interest. Users can also choose amongst the several metadata fields such as host, geographic location and the date of pathogen isolation. Once a particular taxon, strain or metadata category is selected as a search criterion, additional search criteria appear dynamically to allow the users to perform more focused searches. Moreover, users can also use the advanced search options to refine the search results with the more fine-grained search criteria. For instance, users can choose to view data on strains isolated in specific months of a given year(s) or limit search to specific host attributes such as gender and age and choose to limit their search to specific specimen type, laboratory strains and organism detection method. Lastly, users can customize their viewing options to specific display fields through advanced search menu. An example of the various search options is shown in [Fig. 1](#).

Application Programming Interfaces (API)

ViPR and IRD provide users an option to retrieve certain data types using command line utilities via Application Programming Interfaces (APIs). Specifically, the sequence search API allows users to retrieve sequences and associated metadata using GenBank and protein accession IDs. The retrieved sequences can be obtained in either FASTA or JSON formats with user-defined associated metadata. The surveillance API allows retrieval of surveillance records and metadata from host surveillance samples. IRD allows users to submit sequences for large phylogenetic analysis jobs through an API to the high-performance computing environment provided by the NSF-sponsored Cyber-Infrastructure for Phylogenetic Research (CIPRES) Gateway. Tree calculations are made using the high-performance computing environment and the resulting phylogenetic tree is returned for visualization using the Archaeopteryx tool in IRD.

Analysis and Visualization Capabilities

ViPR and IRD host a comprehensive suite of bioinformatics tools for data analysis and visualization, closely integrated with the supported data. These include popular webtools in bioinformatics constructed by the ViPR team or contributed by users/collaborators. Examples of the types of analysis that can be performed and the webtools that are available are described below. For a complete list of analytical tools, the reader is directed to the ViPR (see “Relevant Websites section”) and IRD (see “Relevant Websites section”) homepages.

Sequence Annotation

The sequence annotation pipelines allow users to upload and annotate genomic sequences to predict segment type, CDS location, and genotype information, and to identify possible sequencing artifacts.

Protein Sequence Search ¹

Search for influenza sequences, proteins, and strains using two types of searches. Use the advanced search to allow you to refine your search with the more fine grained search, and you can pick your viewing options.

Clear Search

Fig. 1 Protein search interface in IRD. The search page supports queries based on “classical” as well as “variant” proteins and associated metadata. A search query can be made more specific by choosing various query features. For example, users can search for specific strain(s) by entering the strain name and subtypes in the appropriate search fields. Additionally, choosing a type of host, such as avian, brings a drop down menu from which the user can choose one or more species to make the search criterion more specific. Users may also choose to limit their search results by geographic region(s) by choosing one or more countries in the dropdown menu. Search results may be limited to a specific date range by putting in the years or by choosing a month range through advanced options. Multiple other search criteria such as keyword search, submission date, host gender and age etc. are available through advanced options to make the search results more specific.

Sequence Search and Alignments

Users can use popular tools such as BLAST and MUSCLE within ViPR and IRD. Sequences can be selected from a search result or a working set in their personal workbenches. Users can also perform manual exploration and curation of sequence alignments including relabeling the sequences and adding sequence features. After an alignment is completed, users have an option to download the input sequences and output files in a variety of formats or pass the alignment to another tool including SNP analysis or meta-CATS.

Fig. 2 Example of a phylogenetic tree constructed in ViPR. The search interface was used to retrieve unique sequences belonging to the 450 bp region that codes for the C-terminal 150 amino acids of the N nucleocapsid protein of the human measles *Morbillivirus*. A total of 554 unique sequences were obtained. Multiple sequence alignments were performed with MUSCLE and phylogenetic relationships inferred using RAxML for visualization with Archaeopteryx.js. The legend shows options for users to customize the tree visuals and highlight desired metadata in Archaeopteryx. For instance, the phylogram display with aligned labels has been chosen from the top left panel for improved readability. Likewise, the “Dyna Hide” option on the left panel has been selected to only show representative sequence names. Names of the nodes have been color coded to indicate the year of isolation. The node color indicates the country of origin. The available sequences separate into 3 clades belonging to subtypes D8, B3 and H1. The subtypes are represented in the parentheses following the names of the sequences. While the subtypes D8 and B3 are more globally circulating, causing infections across different countries, the subtype H1 is predominantly found in China. Moreover, in a given country, strains belonging to the same subtype have repeatedly caused measles infections over several years indicating pathogen persistence in the population, likely due to imperfect and inadequate vaccination practices.

Phylogenetic Tree Reconstruction

Users can infer phylogenetic relationships using RAxML and FastME algorithms, and visualize the results using a customized visualization tool developed in house called Archaeopteryx, which allows users to color-code and annotate various tree branches and nodes using available metadata, such as geographical location, host, isolation year, and amino acid residues at user-selected positions (e.g., [Fig. 2](#)).

Metadata-Driven Comparative Genomics

The meta-CATS tool provides a statistical analysis of sequences to identify genome and protein positions that show significantly-different residue distributions between groups of sequences using the Chi-squared statistic. Sequences can be segregated into groups manually or automatically based on selected metadata values, such as year of isolation, geographical location, host species, etc. Thus, a user can put the analysis of sequences in the context of infection and infer association of variations in a genomic region with a particular infection characteristic.

Analysis and Visualization of 3D Protein Structures

Users can search for protein structures using multiple types of queries, including PDB IDs, gene symbol, Entrez ID, UniProt accession, and gene product names. Furthermore, search can be restricted to include only proteins with experimentally determined epitopes, experimentally determined active sites and proteins with sequence features. Additionally, users can use advanced options to query the database using theoretical structures. Once a particular structure from the search results is selected, users can customize the general appearance of protein structures. For example, users can highlight ligands, active sites, epitopes and sequence features on the 3D structures. Individual residues within the protein structures are mapped to homologous positions from UniProt records, which allows comparison between protein structures. Annotating a 3D structure with important residues and regions of interest can yield testable hypotheses about the functional relevance of the protein. Lastly, users can download the highlighted protein structure as a publication quality image file or a structure movie.

Genome Annotation Using VIGOR

Users can use the VIGOR software tool along with its collection of highly-curated reference databases for different viruses to predict viral protein open reading frames and sequences, and to identify typical viral transcriptional and translational exceptions including RNA editing, stop codon read-throughs and ribosomal slippage.

Virus Genotype/Clade Classification

ViPR and IRD offer two types of user/community contributed tools for virus classification. A clade classification tool infers clades for a query sequence from its position within a reference phylogenetic tree. Currently, clade classification is available for Zika virus, and Hepatitis C Virus (HCV) in ViPR and swine H1 and H5N1 influenza viruses in IRD. The H5N1 classification tool uses phylogenetic analysis to classify HA sequences according to the WHO H5 classification scheme. The H5N1 classifier has been verified to have > 98% accuracy for sequences of at least 300 nucleotides of HA1. On the other hand, the H1N1 classification tool in IRD is a robust application of BLAST to recognize sequences closely related to pandemic sequences. BLAST-based classification is also available for classifying rotaA virus sequences in ViPR.

HA Subtype Numbering Conversion

IRD has implemented an HA subtype numbering conversion tool that allows users to convert HA sequence coordinates among any selected subtypes based on protein structure alignment rather than sequence-based alignment. Using this tool, the user can convert the coordinates of an HA protein sequence to the corresponding coordinates in other subtypes, to compare substitutions associated with phenotypic changes and to identify cross-reactive immune epitopes. The tool can also be integrated with sequence variation analysis and meta-CATS.

KEY ANALYSIS FEATURES

- Seamless integration of data and analysis/visualization tools
- Analysis of user data in combination with database data

TOP ANALYSIS TOOLS BASED ON USAGE

- Multiple sequence alignment
- BLAST
- HA numbering
- SNP analysis
- Phylogenetic tree reconstruction
- H5N1 classifier
- H1 classifier

Workbench

Users can establish personal workspaces under the “workbench” feature within the IRD and ViPR. This tool provides an interface that allows users to save previous search or analysis results, which enables users to re-use their work without re-running the analysis. It also allows users to combine multiple analyses. Users can upload and save their own private data and metadata to their

Fig. 3 Links to multifaceted user support available in ViPR.

Fig. 4 The number of peer-reviewed citations for the ViPR and IRD resources.

workspace to be analyzed using the analytical and visualization tools provided by IRD and ViPR. The saved data and analysis results can be shared with collaborators through their workbench accounts.

User Support

The IRD and ViPR databases are open access resources and can be used and shared without restrictions. The databases offer multifaceted user support (Fig. 3). Users can report a problem or ask a question using the forms provided online. The development and management teams of both IRD and ViPR are responsive to questions from the helpdesk and to suggestions for enhancements. Users can join a newsletter mailing list to get information about updates of the resources.

Both IRD and ViPR provide extensive tutorials, training modules and manuals. For additional support, the development and management teams engage in outreach sessions that include webinars, tutorials, and training workshops at various geographical locations. For an expert user, the analytical tools developed by the ViPR/IRD team are also available on GitHub, which avails the user with an option of using the tools outside of the IRD and ViPR resources on their preferred platform.

Usage Statistics

The ViPR and IRD databases continue to provide critical resources in several research studies as evident by the increasing number of citations in the scientific literature (Fig. 4). Together, the two databases have been cited in 1080 publications as of May 10, 2019. The number of new sessions initiated per week in 2018 (Google Analytics) tallies at 1488 at ViPR and 1482 at IRD. Importantly, these sessions have been documented from 181 countries for ViPR and 174 countries for IRD.

Summary and Conclusions

Virology research is dependent on timely availability of reliable data on viral pathogens, their hosts and the infection/outbreak dynamics. ViPR and IRD offer comprehensive, highly curated data on human viral pathogens along with an intuitive search interface and seamless integration of the data with analytical and visualization tools. The resources are available freely without restrictions. The availability of such resources streamlines and expedites experimental discovery advancing the ultimate goal of developing improved diagnostics and therapeutics for priority pathogenic viruses.

Glossary

Protein Data Bank A database for the three-dimensional structural data of large biological molecules (including protein, nucleic acids and viruses).

Similarity score A numerical measure to quantify how similar two or more objects of study are.

Introduction

Classification is the process of discovering what is similar and what is different in a set of objects. In biology, in particular, the classification of organisms has been a major focus since Aristotle, who created a complete order of living things (*"Scala naturae"*). The modern standardized biological classification of organisms was established in the 18th century by Linnaeus, who showed, that a meaningful classification can be established by comparing only selected parts of plants. Then, the first "tree of life" (*"Arbre botanique"*) relating members of the plant kingdom was published by Augustin Augier. Later, taking into account this concept of a tree-of-life, Darwin proposed the theory of natural selection and the theory of descent, which attempted to explain how species emerge. Finally, in 1953, the determination of the structure of the DNA double helix by Rosalind Franklin, James Watson and Francis Crick, and how it carries the genetic information from one generation to the next, enabled a unified basis for the classification at the molecular level of all biological entities on earth.

A simple viral particle consists of the genetic material, DNA or RNA, which is shielded from hostile environments by a protein structure called the capsid which, in turn, can be enveloped by a membrane. A regular sized capsid is formed by one or several types of proteins. As viruses have to pack their entire genome into the capsid, the number of genes encoding capsid forming proteins is severely constrained. Thus, multiple copies of the same protein or proteins are used to build the capsid of a required size. This intricate way of forming capsids from repeating subunits locks the capsid's protein structures from evolving in such a way that the assembly of the whole capsid is jeopardized.

Viruses are obligatory parasites that need their hosts to proliferate, but they do not often offer any direct benefits to their infected hosts. Thus, there is a constant arms race for host cells to evolve and escape viral infections whereas viruses have to adapt to the adapting hosts to generate a progeny. This tug-of-war can be seen in the receptor binding proteins that are under constant evolutionary pressure to change enough to be able to detect and bind the host cells.

Viruses have been classified like any other biological entities ever since their discovery. However, since they are "pseudo-living", their placement within the originally proposed tree of life has been problematic. The earliest proposed virus classification was based on the Linnaean hierarchical method based on virus' shared properties and genome types. In 1966 the International Committee on Taxonomy of Viruses (ICTV) was officially set up to formalize naming conventions and classification guidelines. ICTV defines virus species as: "a polythetic class of viruses that constitute a replicating lineage and occupy a particular ecological niche". Thus, viruses belonging to same species would share common traits like the nature of the genome, morphology and host.

There are also other possible ways to classify viruses such as the Baltimore classification that uses exclusively genome type (*e.g.*, group I: dsDNA viruses and group II: ssDNA viruses) and the replication method as a basis for the classification. Finally, as the virus capsid is considered by some to be the hallmark of the virus ("no capsid, no virus"), the structure-based virus classification has been proposed. In this view, those viruses that share the same fold in the major capsid proteins (MCPs) and the capsid architecture, belong to the same viral lineage regardless of their genome type or the hosts. All in all, the different classification schemes complement each other and highlight the diversity of the virosphere.

Viruses, despite undergoing constant environmental pressure and intrinsic genomic mutations that effectively sample the sequence space, keep the functionalities of their proteins intact, particularly those forming the capsids. Major capsid proteins provide a unique opportunity to develop and test computational methods for structural classifications, as well as to address the question of how the primary structure dictates the three-dimensional functional protein structure.

Aside from the pure academic interest, knowing how different (viral) proteins are related allows the development of new drugs or the repurposing of old ones, *e.g.* for tackling viral diseases. It is also possible to infer functions of newly discovered proteins by comparing them against known proteins. The primary structure – the amino acid sequence – can be used for comparing closely related proteins as the evolutionary trajectory is constrained by protein's function, but for more distant relatives, the tertiary structure – the three-dimensional shape of the protein – is usually far more conserved than the sequence, since the three-dimensional structure, whether being part of the virus or the host is the functional unit. Thus, the tertiary structure allows both (1) long-distance evolutionary studies, *e.g.*, to find homologous proteins where the sequence conservation is lost, and (2) an opportunity to increase our knowledge about proteins' physical properties, *e.g.*, to understand thermodynamic parameters that govern the protein folding process.

With the technological advances to structurally probe biological entities (*e.g.*, X-ray crystallography, high-throughput sequencing and electron cryo-microscopy [cryo-EM]) as well as the greatly increased computational power to process the data, we have now significantly improved our understanding of the living world. This has come with a price: it is no longer straightforward to classify organisms like bacteria into a single tree with a simple top-down hierarchy. This, in fact, does not necessarily depict the real relationships between the bacterial species, which might have acquired whole gene families and new metabolic pathways by horizontal gene transfer. Thus, the current problem of biological classification is that it is based on *hierarchies*, *i.e.*, all objects to be categorized must form a tree-like structure.

Once the central dogma of the molecular biology was established, the early idea of “one sequence – one protein – one function” was quickly discarded as more and more structural data became available and it was observed that proteins with dissimilar sequences might encode highly similar structures. As viruses have to constantly maintain the ability to infect their hosts that are in turn evolving in new ways to evade infections, virus' protein sequences and structures have been essential for understanding the complex sequence-structure relationships. One of the early hallmarks was the observation by Michael Rossmann that the structure of the coat protein of human rhinovirus 14 is surprising similar to that of the plant virus, despite the lack of detectable sequence similarity between the two. However, at the same time, it was observed that the naturally occurring (viral and cellular) protein fold-space seemed to be quite limited. Thus, the biological (macro-)molecules are formed as combinations of common three-dimensional folds.

Ultimately, if one would know how the protein's primary structure (sequence) dictates the tertiary structure, the classification could be directly sequence-based. Currently, the best methods to classify a set of proteins are based on using both sequence and structural information. For the distantly related proteins especially, the ultimately redundant information encoded in their 3D-structures enhances the weak evolutionary signals.

Methods to Compare (Viral) Proteins

The comparable 3D structures are derived using X-ray, NMR, cryo-EM or, in some cases, computational methods. Historically, X-ray has been the main source of atomic resolution structures for proteins (and icosahedral viruses). NMR has been limited to smaller molecules, whereas it is only in recent years that cryo-EM has reached the atomic level.

In sequence comparisons, the nucleotides and amino acids represented by single letters are always in register, *i.e.*, the movement of the primary structures in respect to each other is one-dimensional (left or right) and constrained to have either matching letters denoting the same nucleotide or amino acid, mismatching letters denoting point mutations or gap-letter *versus* nucleotide/amino acid letter denoting insertion or deletion events (called indels) for each position in both sequences. However, even the simplest sequence comparisons can report good matches by chance, in particular if comparing nucleotide sequences. Computationally, sequence comparison is a well understood problem since it can be directly formulated as a dynamic programming problem, where scores of each residue-residue comparison are strictly based on the scoring matrix and previous neighboring comparisons and, the best alignment score can be calculated by progressing sequentially through each individual comparison. However, as the rules of how sequence dictates the three-dimensional structure of a protein are yet to be discovered, the comparisons with the current methods tend to break down with highly diverse proteins, often found in viruses.

The tertiary structures (with the assumption that they are at the same scale) have six degrees of freedom (three axes to move structures relative to each other and three rotational axes) making the alignment computationally more demanding and the exhaustive search impractical. On the other hand, structural similarities last longer in the evolutionary timescales, thus it is possible to study remote homologs with structural comparisons even when the sequence similarities cannot be detected using current methods. **Fig. 1** shows an example of how viral coat proteins with rather different protein sequences can be aligned accurately based on their structural properties.

The earliest method of comparing two protein structures was visual comparison by eye. There, the protein structure coordinates were visualized together and then aligned to each other by moving and rotating structures. The proper alignment needed an expert to decide when the equivalent parts of the proteins were aligned. Usually, the C α atoms were considered for the alignment for simplicity and efficiency. After the alignment, one could calculate a Root Mean Square Deviation (RMSD, the square root of the averaged sum of the squared differences of the C α distances) between the relevant parts of the structures. The alignment by eye becomes cumbersome and error-prone when there are more than a few structures to compare.

Fig. 1 Sequence vs. structure alignment. How sequence alignment differs from structural alignment. (a) protein sequences of bacteriophage Q beta (family *Leviviridae*; genus *Allolevivirus*; PDBid 1QBE_A) and bacteriophage PRR1 (family *Leviviridae*; genus *Levivirus*; PDBid: 2VF9_C). Viruses in the *Leviviridae* are small RNA-viruses known to have very high mutation rate. (b) left: dotplot of protein sequences with wordsize 1. If there were significant sequence identity, the diagonal would be filled with points. Right: Needleman-Wunsch sequence alignment. Sequence similarity is 36.1% (52/144). (c) Secondary structure visualizations of the 1QBE_A and 2VF9_C. (d) left: dotplot of the equivalent residues based on HSF-program. Right: the superimposition of the structures.

Fig. 2 Clustering of multiple structures and effects of adding structures into the data set. (a) line representation of hypothetical protein structures to be clustered. Each “structure” (e.g., structure A) has several “domains” colored separately. (b)–(e) “phylogenetic” trees based on structural similarities when more and more structures are added and cluster boundaries/tree branches change. In the beginning (panel b)) the structures A, B and C are equally apart. In (c) adding structure D causes clustering of B and D together and A and C together. In (d) adding structure E causes structure B to radically change from being closest to D to being closest to structure C. In (e) added structures F and G push structure A farther away from original structures B and C, but at the same time two sides of the tree (E, D and A vs. C, B, F and G) have enough close relatives that the distances and the local topology stabilizes. Structures H and I show difficulties when comparing to already clustered structures. Structure H has rearranged domains, thus making it difficult to place into the final tree. Structure I in turn shows how movement of parts of the protein structure makes especially rigid body alignment hard to solve.

The first automated methods for structural alignment were devised in the early 70's and the fundamental question for comparing a set of proteins became evident: what is similar and what is different and how to quantify those similarities and differences. The similarity measures between two proteins need some definition of the concept of *equivalence*. In the geometrical case, equivalent residues can be thought to be those that superimpose well on top of each other when the rigid structures are aligned. How to define which residues in two structures are equivalent algorithmically is similar to the “point pattern matching problem” in image processing whose exact solutions are computationally very hard to find [*i.e.*, the non-deterministic polynomial acceptable problems (NP-hard) in computer science]; in other words, neither fast nor universal methods are known. Thus, all practical methods to establish equivalence between residues use heuristic techniques.

There will not be scaling or perspective to worry about if we are at the atomic resolution level. The three dimensional matching even without considering scaling is still a hard problem computationally. There are again six degrees of freedom (three rotational and three translational ones) assuming that the matching points between different point clouds (e.g., C α positions of protein residues in space per compared structure) are known. If there is ambiguity in point-matching or if there are more points in one cloud compared to another, the problem becomes even harder.

It is important to understand that the geometry (*i.e.*, position of the atoms in the 3D-space) does not entirely cover the question of the similarity (see Fig. 2). Proteins are highly dynamic in the cell and their conformations depend on the circumstances e.g., possible binding of cofactors. A typical example, calmodulin, has two distinct conformations when binding calcium ions: an open one without calcium ions (PDBid: 1CFD) and a closed one with those ions bound to the protein (PDBid: 1CLL). The amino acid sequence for both conformations of the protein is of course the same, but a rigid body structural alignment taking into account only their geometries could only align one of the two globular domains per structure when comparing the open and closed form structures to each other.

Thus, the biologically relevant computational methods dedicated to protein comparison cannot rely only on the global structural superimpositions. An early step towards more realistic comparisons was to compare the intramolecular distances instead of the intermolecular ones (e.g., equivalent C α distances). Regarding the intramolecular methods, the idea is to calculate distance maps from each structure to compare and then calculate a similarity score based on the similarity of the relevant parts of those maps. The distance maps are rotationally and translationally invariant *i.e.*, independent of the orientation of the molecule, therefore, the structures do not need to be superimposed in 3D in order to find similarities. For example, in the calmodulin case, both globular domains retain their internal distances at the open and closed conformations, thus giving higher similarity scores compared to simple rigid body superimposition and RMSD. There are several different approaches to calculate and compare intramolecular distances. Some methods (e.g., DALI) use the complete distance matrices to find regions of similarity whereas other methods (e.g., Combinatorial Extension) combine and compare larger sets of residues using a dynamic programming approach.

It is also possible to “scale back” from the purely atomic level comparisons and to compare derived properties that comprise larger, functionally important, subunits of proteins like secondary structures (e.g., helices and β -sheets) up to “super secondary structures” *i.e.*, continuous folds (e.g., whole domains). The property-based classification methods can be either based on

superimposition of the subunits or they can be alignment free (*e.g.*, based on comparing frequencies of the properties). The currently best methods for protein structure comparisons are using hybrid methods, where different properties of the proteins are considered together.

There are many different methods to compare structures. Similarly, there are several distinct methods to evaluate the quality of the alignment (*i.e.*, scores). The most used ones are calculated from aligned C α -atoms: the earlier mentioned RMSD and the Z-score, developed for the DALI-method that uses distance matrix element differences from compared structures.

As with sequence alignments, once pairwise alignment is defined, multiple alignment remains problematic. It is possible to use the multidimensional dynamic programming approach for exact multiple sequence alignments, but it is an infeasible task for more than three sequences of modest length in terms of computational resources (time and memory).

One particular method that combines several approaches and levels of representations is implemented in the Homologous Structure Finder (HSF) software. HSF integrates several different ideas of the structural alignment and classification of multiple protein structures in a single extensible framework. It has been inspired by earlier software such as COMPARE and Structure-Homology-Program (SHP). COMPARE is the first software to take into account several levels of data. However, the levels (*e.g.*, the secondary structures or C α -positions) are handled separately. On the other hand, SHP effectively uses Argos & Rossmann's idea of probabilities to find an optimal alignment of the C α -atoms through a path of dynamic programming matrix. A distinctive feature of the HSF, when deriving the alignment of multiple structures, is the construction of a consensus structural *core*. This core may not resemble the true 3D (sub)structure of any of the structures in the data set and it does not have to follow the linear representation of any of the protein sequences, but it is rather a set of all residues that are equivalent for all structures. Logically, the core should closely resemble the original 3D-structures, if the structures themselves are very similar to each another. The concept of core also enables structural classification of very localized, yet highly conserved, structural features like ion-binding sites, where the position, rather than the type of amino acid, is critical for the establishment of the binding site.

The HSF calculates the final core by doing all-against-all pairwise comparisons of cores in an iterative manner. After each step, the cores yielding the best score are merged to a new core which then represents merged cores in the next iteration. Initially, each structure is considered as a single individual core comprised of all residues. The core can then be used to calculate scores between different structures and the scores then can be converted, in turn, to distances to calculate the final "phylogenetic" tree. Using the core allows one to compare only those parts of the structures that are guaranteed to be present in all structures.

There are two main categories of comparable properties in HSF: invariant and dynamic. Invariant properties (*e.g.*, electric charge and hydrophobicity of a residue) are such that they do not change when structures are moved with respect to each other in the 3D space, whereas dynamic properties (*e.g.*, C α -C α distances) change accordingly. All comparisons of properties are represented as individual matrices of equivalent residues. The way properties are compared depends on the property itself. For example, local geometry or simply sequence similarity can be compared, but understandably both have very different comparison methods. The property matrices can be further used to derive new matrices *e.g.*, a matrix representing secondary structure comparisons between two cores.

As at the start there is no spatial information about distances between residues, HSF takes an unsupervised approach for the initial choice of the equivalent residues by selecting the most probable equivalent residues based only on the invariant properties. After the initial assignment, the first superposition is performed per equivalent residues. After that, the new equivalences are assigned based on the weighted sum of invariant and dynamical properties with an iterative process of superposition and assignment. HSF has been able to classify automatically the PRD1-adenovirus lineage structures (see below) as well as to define a conserved structural core for the non-catalytic ion-binding site in multiple viral RNA-dependent RNA polymerases.

Incorporating Different Levels of Data to Structural Alignment and Classification

Practically, all modern tools for classifying atomic structures use several different layers of data (*e.g.*, sequence-, secondary structure- and 3D-information). The HSF software is not an exception and it already incorporates several properties derived from both sequences (*e.g.*, physiochemical properties of amino acids) and 3D structures (*e.g.*, local dihedral angles and secondary structure information). However, it is still possible to further constrain the classification process with atomic-level information by using for example the overall resolution of the structure and the B-factors per atom. There is also a wealth of other data available from laboratory experiments like protein-protein interactions, cellular localization, biochemical functions and other experimental evidence of biological processes and pathway associations. Indeed, pre-existing annotations are being taken into account, for example, to select the structures in the initial data sets, but since annotations might be also misleading and lead to circular reasoning in separating the classes, they should be used carefully. This is particularly relevant when considering viruses, because the taxonomical assignments can change radically when new viruses are discovered (Fig. 2).

Databases for Structure-Based Classification

Although there are no dedicated structural classification databases for viruses alone, several databases (*e.g.*, SCOP, CATH, HOMSTRAD, FSSP, PDBFold, PFAM) exist that use various methods to classify protein structures or single folds into hierarchical manner. The most widely used ones are SCOP (Structural Classification of Proteins) and CATH (name based on the four levels of classification: Class, Architecture, Topology/fold and Homologous superfamily). Both are viewed as gold standards and they rely

on both expert curation and also automated methods being able to keep up with the current data accumulation. The PDB itself provides classification for known structures with closest structural neighbors by using the jFATCAT-rigid algorithm.

As an example of viruses' uniqueness in structural databases, bacteriophage PRD1's P2 receptor binding protein (PDB ID: 1N7V) has currently no structurally similar entities in the PDB, apart from the same structure in a different crystal form, and no structural neighbors for any of the domains in CATH database. By contrast, *Rattus norvegicus*' Neuroligin-1 protein (PDB ID: 3BIX) has 39 structurally similar entities in PDB and 252 representative domains in CATH.

It is an open question whether protein folds can be classified in discrete hierarchical classes at all, since there is evidence that suggests that the fold space might overall be continuous. A recent version of SCOP (SCOP2) has tackled this problem by replacing the simple taxonomy-like classification with directed acyclic graphs to better capture possible different relationships (*e.g.*, structural and evolutionary relationships are separated).

Inferring Phylogeny Based on Structural Data

Once the classification has been performed for a set of structures, the question is then how to utilize this information to decipher possible evolutionary relationships among the proteins. The most common route is to mimic how sequence alignments are used to generate phylogenies. Like with pair-wise or multiple sequence alignment scores, the structural alignment scores can be converted to estimate "evolutionary distances". The distances can then be used to build an unrooted tree using for example the *de facto* standard phylogenetic analysis package PHYLIP.

Nevertheless, it is not yet clear how accurately the calculated structural distances truly correspond to evolutionary distances, since there is no fossil or archeological data to calibrate the molecular clock for macromolecular evolution. Applied to previously characterized protein families, the structural classification-based phylogenies correspond well to studies using sequence-based protein coding genes. Furthermore, structural phylogenies have been able to unveil distant evolutionary relationships, even when the protein sequences have mutated beyond detectable similarity.

Case Study: Past and Present of the Structure-Based PRD1-Adenovirus Viral Lineage

The finding that both lipid-containing bacteriophage PRD1 and eukaryotes-infecting adenoviruses possess an MCP with a vertical double jelly-roll (DJR) fold has been instrumental in establishing the structure-based approach to infer viral phylogeny. This fold entails two single jelly-rolls connected by a short linker; each jelly-roll consists of eight beta strands arranged in two four-stranded antiparallel beta sheets packed together (topology of one single jelly-roll shown in Fig. 3(a)). The power of the structure-based classification to infer viral phylogeny has been strengthened by the addition of several viral protein 3D structures determined during the last 15 years. The first viral MCP structure-based phylogenetic tree published by Bamford, Grimes and Stuart (see Section "Further Readings") for the PRD1-adenovirus lineage contained three virus members: PRD1, adenovirus and PBCV-1 (Fig. 3(b)). The latter virus was the largest of the three with a diameter of ~ 1900 Å. The assumption that coat protein topology and virion architecture could be used as fossil fingerprints led some of us to explore the use of this approach in grouping other viruses with MCPs with a different fold (a dedicated article can be found elsewhere in the Encyclopedia). It was postulated that viruses could be structurally classified in four lineages initially called PRD1-like, HK97-like, BTV-like and picorna-like. Currently, the classification of the virosphere using the above four structure-based viral lineages accounts for more than 30 viral families, in contrast to the grouping in "order" and "families" used by the International Committee on Taxonomy of Virus (ICTV) until 2019 which accounted for 22. Very recently, however, due to the accumulated evidence of distant viral relationships the ICTV classification scheme has been substantially expanded.

Focusing on the first established PRD1-adenovirus lineage, over the years the members of this lineage have been expanding in some cases leading to unexpected insights. Chronologically, after the structure determination of the hexon MCP (adenovirus), P3 MCP (PRD1) and Vp54 MCP (PBCV-1) for which also the complete virion structures were available and showing the use of pseudo-hexameric capsomers (trimers of the MCP) as their assembly building blocks, two more MCPs were determined by X-ray crystallography: the MCP of membrane-containing Sulfolobus turreted icosahedral virus (STIV), the first virus infecting an archaeal host displaying a DJR capsid protein and the major coat protein P2 from the marine lipid-containing bacteriophage PM2. STIV MCP not only exquisitely superimposed onto the available MCPs of the PRD1-adenovirus lineage but its modeling into the virion map at the time supported a similar principle for virus assembly.

P2-PM2 was the first – and still remains the only – MCP with a minimalist double jelly-roll serving as the simplest prototype for the PRD1-adenovirus lineage. Structural superimposition of the two individual jelly-rolls of P2 (V1, residues 1–141; V2, residues 142–269) shows that they are more similar to each other (2.4 Å rmsd for 116 C α s; 14% sequence identity) than in the corresponding single jelly-rolls from other members of this lineage (Fig. 4). This supports the proposal that the P2 protein arose by gene duplication, suggesting that PM2 virion is more similar to the last common ancestor for this lineage.

It came as a surprise when the structure of vaccinia virus (VACV) D13 protein was solved by X-ray crystallography. Vaccinia virus belongs to the *Poxviridae* family and is characterized by a brick-shaped morphology (not icosahedral as in all previous mentioned viruses) with a lipoprotein surface. D13 is not part of the mature virion but is used as a scaffolding protein during VACV morphogenesis. It was noticed that during virus assembly and maturation, D13 is capable of forming a transitory spherical honeycomb structure providing curvature and rigidity to the convex forming membrane. The building blocks of this layer were trimers of D13 with an apparent pseudo-

Fig. 3 (a) Example of topology of one of the two single jelly-rolls of the DJR PRD1 P3 MCP: the V1 jelly-roll (strands labeled as BIDG/CHEF), the dark-blue and red circles being respectively the N-terminus and C-terminus of V1 (residues 15–245). (b) First structure-based phylogenetic tree published in 2005 for the definition of the PRD1-adenovirus lineage and obtained using the SHP and PHYLIP software; the sequence identity across the three MCPs is at the most 18% (in the case PRD1 vs PBCV-1). On PRD1 P3 MCP the two single jelly-rolls are marked as V1 and V2 (residues 246–383); across the three MCPs the V1 and V2 are colored in distinct shades of green and red. Adapted from Bamford, D.H., Grimes, J.M., Stuart, D.I., 2005. What does structure tell us about virus evolution? *Current Opinion in Structural Biology* 15, 655–663.

hexameric morphology. This morphology recapitulated the organization of the capsomers formed by the viral DJR MCPs onto the virus facets. Ultimately, the crystal structure revealed that D13 possesses the DJR fold with a “turret” domain as an elaboration of a loop at the top of the V2 domain. Its structure was strikingly similar to the MCPs of the members of the PRD1-adenovirus lineage (Fig. 4).

The structural sampling of the viral world also led to the determination of the MCP structure of Sputnik virophage by cryo-EM to 3.5 Å resolution. Sputnik is a satellite (non membrane-containing) virus of the giant Mimivirus which infects *Acanthamoeba polyphaga* cells. While the MCP of Mimivirus has yet to be determined (there is the proposal that it might possess the DJR fold), the MCP of Sputnik was resolved thanks to the high quality of the virion cryo-EM map. Its overall structure displays a DJR fold with the classical BIDG and CHEF strands and, despite its variation on the structural motifs placed at the top of the single jelly-rolls, it fits nicely in the PRD1-adenovirus lineage (Fig. 4). With the identification of Mimivirus, about 5000 Å in diameter, the perception of viruses as small entities faded away. To date, several even larger viruses have been identified grouping into the assemblage informally known as nucleocytoplasmic large DNA viruses (NCLDVs) and recently officially classified into a phylum *Nucleocytoviricota*. Faustovirus, about 2600 Å in diameter, infects amoeba and its overall structure was resolved by cryo-EM at 15 Å resolution. Strikingly it showed two almost juxtaposed proteinaceous layers. The outermost capsid is organized in capsomers with a pseudo-hexameric appearance consisting of trimers of the MCP which possess a double jelly-roll fold as determined by X-ray crystallography. The capsomers are crowned by large and structured insertions in loops connecting the DE and FG β -strands above the two V1 and V2 β -barrels that protrude toward the outside of the virus.

Exploring novel ecological niches, specifically a Finnish boreal fresh water habitat, the identification and structural characterization of *Flavobacterium*-infecting, lipid-containing phage (FLiP) described a phage with a circular ssDNA with an MCP with a DJR fold structurally closer to PRD1 and PM2 MCPs (Fig. 4). This represented a clear evidence of evolutionary relatedness between icosahedral ssDNA and dsDNA viruses. FLiP rolling-circle replication and structure testify the possible combination of different replication mechanisms with architecture and assembly principles recapitulating those of the PRD1-adenovirus lineage. The latest addition to this lineage has been African swine fever virus (ASFV). ASFV is the etiological agent of a swine viral disease present in

Fig. 4 Current structure-based phylogenetic tree of the PRD1-adenovirus lineage. Structural alignment and evolutionary distances performed with HSF and unrooted phylogenetic tree depicted using PHYLIP. In cartoon and to scale the MCPs corresponding to the different viruses (PRD1: PDB ID 1HX6; PBCV-1: 1M3Y; adenovirus: 1P2Z; STIV: 2BBD; Vaccinia D13: 2YGB; Sputnik: 3J26; Faustovirus: 5J70; FLiP: 5OAC; ASFV p72: 6KU9; PM2: 2W0C). Numbers next to each branch indicate their corresponding lengths (evolutionary distances).

many of the countries in Africa, Europe, and Asia. Due to its recent devastating effects on worldwide pig population, several laboratories have independently determined by cryo-EM its 3D structure and the structure of its major protein components. Strikingly, ASFV virion, with a radial diameter of ~ 2080 Å, displays a unique architecture comprising two icosahedral capsids and two lipoprotein membranes. The outermost capsid shell is composed of 8280 copies of MCP p72, which possesses a DJR fold (Fig. 4). Interestingly, p72 MCP clusters closer with the MCPs of the other NCLDV, and in particular, faustovirus. This NCLDV clustering indicates that structural differences exist in the core consensus DJR and this difference might recapitulate the requirement of these MCPs to stably assemble the largest capsids of this lineage.

In conclusion, the conceptualization of the structure-based PRD1-adenovirus lineage has served to define a new approach to identifying common ancestry, not only within the member of this same clade but across the different known viruses populating the virosphere. The PRD1-adenovirus lineage is nevertheless steadily expanding and providing further evidence for an evolutionary descent across different viruses. In the new ICTV ranking all DJR are now classified as Kingdom (official taxon) carrying the taxon name of *Bamfordvirae*. It is likely that this lineage (or Kingdom) will accrue more members as recently it has been suggested that a new tentative family of viruses called *Autolykiviridae* may also possess MCP with a DJR fold. Further, the recent structure determination by high-resolution cryo-EM of novel viruses with two vertical single jelly-roll MCPs (*Spherolipoviridae* family) forming capsomers with a pseudo-hexameric footprint is also contributing to deciphering the evolutionary relatedness between these viruses and those of the PRD1-adenovirus lineage. In this light, it is enticing to speculate the existence of an ancestral virus with only one vertical single jelly-roll MCP capable to assemble into pseudo-hexameric capsomers that would anticipate the assembly of viruses of the PRD1-adenovirus lineage. The search is on!

Conclusions and Future Perspectives – New Methods for Classifying Biological Entities Including Viruses

The known protein universe is highly diverse from the sequence point-of-view, especially for viral proteins, whereas the actual fold-space is constrained to a handful of common folds. Having atomic level information of proteins therefore enables

classification at the longer evolutionary timescales. This, in turn, is essential to understand protein-protein interactions within the viral capsids and to recognize active sites when only the amino acid position in 3D structure is conserved.

The current high-throughput data acquisition methods and initiatives like Structural Genomics initiative produce enormous amounts of both sequence and structural data. In particular, cryo-EM methods have progressed to be able to routinely reach atomic resolutions and the derived protein structures can now be used along with the crystal structures. With sequence based viral phylogenetics, it is possible to estimate molecular clock for highly mutating RNA-viruses by yearly sampling and sequencing. So, theoretically, similar method could be also used for generating data to calibrate molecular clock for structural phylogenetics.

Currently, there are tens of tools comparing and aligning protein structures. Thus, the alignment problem and especially the alignment of multiple structures is an active and important area of research with real life implications *e.g.*, for understanding the molecular principles of disease causing mutations and for developing antiviral drugs. Some of the challenges that lie ahead for computational classification based on structural data are – to mention a few: (1) how to compare intrinsically disordered proteins; (2) how to perform alignments of flexible domains efficiently and (3) to score such alignments. To infer structural phylogenies, one of the questions is whether it would make sense to describe some of the evolutionary relationships between multidomain structures as set of trees or networks of protein domains instead of a single tree-like hierarchy.

There are also completely new computational methods: for example the Helsinki-Okinawa sequence similarity (HOSS) tool, that allows us to penetrate further into the ‘Twilight Zone’ of the sequence similarity and so being able to reconstruct the PRD1-adenovirus lineage from sequences directly. Similarly the AlphaFold algorithm, a recent breakthrough that can predict in certain cases protein structures from sequences alone.

In conclusion, with the current experimental and computational methods we are approaching a level that at least allows us to efficiently use the rules that govern protein folding. It is also foreseeable that in the future new computational methods relying on vast sequence and structural databases and advanced machine learning approaches (*e.g.*, deep learning with recurrent neural networks) will finally bring us to a point where a complete protein structure can be inferred from the sequence alone.

Glossary

Lysogeny Non-productive virus life cycle where viral DNA is integrated into host genome or replicated independently while the host growth is not affected and no new virus progeny made. See also provirus.

Lytic life cycle Productive virus life cycle where new virus progeny is made and released by host cell lysis.

Plaque Originates from a single virion initially infecting a single cell. Visible area on dense host lawn caused by virus replication and result of host cell lysis or growth inhibition of host cells.

Provirus A viral genome integrated into the host genome.

Replication cycle Refers to events where viruses use host's cellular machinery and metabolites to make copies of

themselves. It involves host recognition, attachment, entry, uncoating, genome multiplication, mRNA and protein synthesis, assembly, and release.

Sedimentation rate Of a particle is the speed of the travel in solution subjected to high force of gravity (g-force) upon centrifugation.

Svedberg unit (S) is a measure of the sedimentation rate of a particle when subjected to centrifugation.

Temperate virus A virus capable to replicate by lysogenic and lytic cycles.

Virion Infectious mature virus particle.

Virulent virus A virus replicating via lytic cycle.

Bacterial and Archaeal Viruses Come in Different Sizes and Form a Polyphyletic Group of Viruses

Viruses are large macromolecular complexes capable of transmitting their genomes from a host cell to another. Bacterial viruses (i.e., bacteriophages) and archaeal viruses infect prokaryotes (bacteria and archaea) that are single-cell organisms lacking a nucleus and organelles. Viruses of bacteria and archaea are polyphyletic in their origin and form a diverse group of viruses differing in terms of virion morphologies, genome types, sequences, life cycles, and host ranges. There are also a substantial number of proviruses found in the chromosomal sequences of bacteria and archaea. Currently the archaeal and bacterial viruses i.e., prokaryotic viruses, have been classified by the International Committee on Taxonomy of Viruses (ICTV) into ~30 families, but there are also a significant number of unclassified prokaryotic viruses. The recent burst in sequence data of prokaryotic virus genomes has revealed that viruses are more diverse than previously recognized. Thus, the current official taxonomic framework of the ICTV does not adequately reflect their evolutionary relationships.

Bacteriophages come in many sizes and shapes that include icosahedral, enveloped, pleomorphic, and helical morphologies, and combinations of these, whereas the virion morphotypes of isolated archaeal viruses are even more versatile (Fig. 1). Some of the virus morphotypes such as icosahedral tailed and icosahedral internal membrane-containing virus types are shared by archaeal and bacterial viruses, whereas certain morphotypes, such as spindle-shaped, bottle-shaped, and droplet-shaped, are specific for archaeal viruses only and have not been discovered for viruses infecting bacteria or for eukaryotic viruses (Fig. 1). The size range of the prokaryotic virions varies from ~25 nm (e.g., bacteriophage ϕ X174 in the family *Microviridae*) to large and complex jumbo bacteriophages (e.g., *Bacillus megaterium* phage G, an icosahedral tailed virus in the order *Caudovirales*) with a capsid size of ~160 nm and a tail length of ~450 nm. Filamentous single-stranded (ss) DNA phages can be long and their length is mainly dependent on the genome size. Lengths of inoviruses range from ~700 nm to ~3700 nm for *Pseudomonas* viruses Pf3 and Pf4, respectively. Additional diversity to the virus morphologies is obtained due to the variations in appendices on the virion surface e.g., spikes and tails that play a role in host recognition and thus vary a lot between viruses. Viruses with highly symmetric icosahedral particles (e.g., family *Corticoviridae* and order *Caudovirales*) produce a very homogenous population of progeny virions. In some virus systems that include pleomorphic or

Fig. 1 Virion morphotypes of bacterial and archaeal viruses. The virus family or order based on the ICTV for each morphotype are indicated. The schematic presentations are not drawn on scale.

spindle-shaped archaeal viruses (families *Pleolipoviridae* and *Fuselloviridae*) particle sizes and morphologies can be more variable due to the floppy appearance of the formed particles and the random distribution of surface structures.

At the simplest, virions i.e., the infectious mature virus particles, consist of a protective shell made of protein and nucleic acid that is encapsidated inside the shell. Virus proteins are mostly encoded by viral genes and can have very different physicochemical properties based on their amino acid compositions and tertiary structure. Some prokaryotic viruses have lipids in their virion. Viruses typically do not have lipid metabolism and the lipids are acquired from the host cell membranes during virus assembly. Viral lipid composition can be identical to that of host, but some viruses favor selective uptake of the host lipid species. Viral lipids are either in the form of an internal membrane vesicle underlying the icosahedral protein capsid (e.g., viruses in the families *Tectiviridae*, *Corticoviridae*, *Turriviridae*, *Fimlakeviridae*, and *Spherolipoviridae*) or as an outer envelope e.g., *Pseudomonas* virus $\phi 6$ in the family *Cystoviridae* (enveloped bacteriophages with a double-layered protein capsid) and *Acidianus* virus AFV1 in the family *Lipotrixviridae* (filamentous archaeal viruses). Lipid modifications can also be found as in the case of the major capsid protein of the spindle-shaped *Haloarcula* virus His1 (family *Halspiviridae*). Pleomorphic virions of the viruses in the families *Plasmaviridae* (bacteriophages) and *Pleolipoviridae* (archaeal viruses) resemble simple extracellular membrane vesicles. Bacteriophage genomes can be either DNA or RNA – single-stranded (ss) or double-stranded (ds). The known DNA genomes of bacteriophages are circular or linear, whereas ssRNA genomes are circular and dsRNA

genomes are segmented. No RNA genome is known for archaeal viruses, their genomes are either dsDNA (circular or linear) or ssDNA (circular). The most common genome type among the archaeal and bacterial viruses is dsDNA.

Virions have a dual role. They have to be stable enough to protect the genome but also capable to attach to an appropriate host cell, to disassemble, and to deliver the viral genome into the cell. Consequently, virions are metastable structures able to change their conformation. Viruses utilize various strategies to be able to fulfill the two opposite tasks. Thus, the particles respond differently to fluctuating physico-chemical conditions and are dependent on variable compounds e.g., divalent cations or a certain pH for integrity and optimal infectivity. Archaeal and bacterial viruses originate from moderate to very extreme environments and have adapted to “live” with and within their host cells. Consequently, the requirements for viral growth and maintaining the stability and infectivity of the virions are very diverse. The sensitivity of the virus and its host to pressure, oxidation, temperature, pH, high or low ionic strength etc. has a major impact on the virus production methods that can be applied and also affects the feasibility of the scale up process.

Isolation and Culturing of Bacterial and Archaeal Viruses

Viruses are ubiquitous in microbial ecosystems and their abundance (estimated to be over $\sim 10^{31}$) is a hundred-fold higher than the total cell number on Earth. Metagenomics approaches have demonstrated that viruses represent the largest reservoir of genetic diversity on the planet. Viruses play significant roles in microbial ecosystems and in microbial evolution and pathogenesis, and influence host population dynamics and their mortality, hence affecting microbial processes and nutrient cycling. Bacterial and archaeal viruses can be found wherever their host cells inhabit. Water, soil, and sediments are full of prokaryotes and their viruses. Some, often extreme biotopes, such as highly saline or high temperature acidic environments, are enriched with archaea.

The basic method of phage and archaeal virus isolation has remained unchanged since the discovery of bacteriophages by Felix d’Herelle 1917. The first archaeal virus was found later in 1974. During recent years, there has been a burst of new archaeal viruses described especially for euryarchaea and crenarchaea. The simplest way to isolate bacteriophages and archaeal viruses is to mix a virus-containing environmental or clinical sample with a potential host strain(s) in appropriate growth conditions typically selected based on the host strain growth requirements. After incubation of the virus-host mixture (enrichment culture), the cells are removed by centrifugation or filtration or a combination of both and the presence of viruses assayed from the supernatant or filtrate flow-through. The most evident sign of a new virus is a plaque formed on a lawn of susceptible host strain cells (**Fig. 2(a)** and **(b)**). The plaques can be clear or hazy depending on the way the viruses are released from the cell (see below). Sometimes enrichment cultures are not necessary and samples with a high concentration of viruses can be plated directly with a susceptible host strain to isolate new viruses. In a hunt for new viruses, it is important to control that the strains used for isolation are not releasing temperate viruses in the applied experimental conditions.

Currently available techniques limit the diversity of viruses that can be isolated, since all of them induce a bias towards those viruses that can multiply most efficiently under the experimental conditions selected. In addition, it has been estimated that less than 10% of all microbes can be cultivated in laboratory conditions. However, several parameters can be optimized including the composition of the growth media, growth temperature and aeration to permit greater success in virus isolation. To obtain further insights into the real diversity of viruses and to initiate in-depth studies on virus-host interactions of ecologically relevant virus-host systems, future work should focus on improving growth methods and developing new microbial cultivation protocols. Importantly, experimental laboratory work on well-defined virus-host model systems isolated from environmental samples provides tools to understand the immense genetic diversity and the role of viruses in the ecosystems and enables studies of virus function at a molecular level and structures up to high-resolution.

There is no single method to isolate a new virus. The best way to start is to go where the potential host strains are. The virus isolation can be accomplished on a single prokaryotic strain, but utilization of a mixture of multiple host strains or multiple strains of the same species usually increases the probability of finding a virus. In the case of multiple hosts, however, it is essential to test them for antagonism that could suppress or interfere with the growth of other microbial species or strains. Use of autochthonous host strain isolates originating from the same environmental samples might also increase the probability for successful virus isolation. Traditionally, most viruses have been isolated by first culturing their hosts and afterwards isolating viruses for the established archaeal or bacterial culture. Obviously, selected growth conditions and isolation hosts set the limits for viruses to be found. In addition, practical reasons play a role when choosing the isolation host: challenging laboratory growth conditions or pathogenic bacterial strains limits their easy use. Importantly, even though a virus was originally isolated from a certain host, it may not be optimal for virus growth and higher efficiency of plating (EOP) may be possible on alternative host strains that can be advantageous in subsequent purification attempts. Non-pathogenic variants of the host species are often beneficial when setting up model system for laboratory experiments.

Prior to virus isolation, the autochthonous cells are usually removed from samples to avoid multiplication of the cells during the enrichment thus allowing specific selected host strains to be used as baits for viruses. However, sometimes the endogenous host strains present in the sample can be beneficial for multiplication of viruses during enrichment culturing. In general, any bias introduced by sample processing should be avoided whenever possible. For samples with low virus concentration, utilizing filtration, precipitation or a combination of both (see below), before the virus isolation may be advantageous. Chloroform treatment of samples is occasionally used during virus production and storage to remove the cellular organisms from samples or to release some viruses from the cells. However, extra caution is needed when using chloroform, since its usage limits the potential to isolate and grow both membrane-containing and filamentous viruses. Even some icosahedral tailed viruses are inactivated or their infectivity is reduced in the presence of chloroform.

Fig. 2 Plaque morphologies. (a) Clear plaques and (b) hazy plaques on a host cell lawn (yellow). Each plaque originates from a single virus infection and can be used to enumerate the number of infectious viruses in the sample. Virus infection can induce (c) host lysis (the life-cycle of the archaeal icosahedral tailed virus HHTV-1 in *Haloarcula hispanica* as an example) or (d) retardation of host growth in the absence of lysis (the non-lytic life-cycle of the archaeal pleomorphic virus His2 in *Haloarcula hispanica* as an example). Consequently, viruses causing host lysis can be typically observed as clear plaques (see Panel a), whereas viruses inhibiting the host growth can be observed as turbid plaques (see Panel b). The onset of lysis and the amount of host growth retardation is specific for each virus-host system and can vary from tens of minutes to several days depending on the host physiology as well. Turbidity of the uninfected (black circles) and infected (black triangles) cultures; the number of free progeny viruses (plaque forming units/mL; pfu/mL) in the infected cultures (gray bars); and the number of viable cells (colony forming units/mL) at 25 h post infection in the uninfected (black arrow head) and infected cultures (white arrow head) are shown. The Panels c and d are modified from Svirskaitė, J., Oksanen, H.M., Daugelavičius, R., Bamford, D.H., 2016. Monitoring physiological changes in haloarchaeal cell during virus release. Viruses 8, 59. doi:10.3390/v8030059. Copyright © 2016 by the authors; licensee MDPI, Basel, Switzerland. After successful virus isolation, pure virus cultures are obtained by a subsequent single-plaque purification technique. Prokaryotic viruses have two major life cycle strategies. They can be virulent and capable of conducting their replication cycle in a cell releasing progeny virions by host cell lysis (lytic replication cycle). Temperate viruses can follow two alternative replication cycles: lysogenic and lytic. During the lysogenic cycle, the virus genome is reversibly integrated into the host chromosomes or replicates as a plasmid (or episome) in such a way that it does not lead to virus progeny production. This “silent” viral genetic element that is part of the host chromosome is called a provirus. They are numerically very significant components of bacterial and archaeal genomes. Spontaneously or under certain conditions, proviruses can switch to a lytic virus replication cycle. To isolate such viruses, proviruses can be induced from bacterial and archaeal strains by physiological stimuli (e.g., elevated temperature for psychrophiles or lowered ionic strength for halophiles) or exposing the strains to inducing agents that impair DNA integrity and cause DNA damage (e.g., mitomycin C and ultraviolet light). Culture-based experimental work on lysogenized strains has resulted in a number of new recent virus isolates e.g., the temperate *Aeropyrum pernix* spindle-shaped virus 1 and *Aeropyrum pernix* ovoid virus 1 of the hyperthermophilic archaeon *Aeropyrum pernix* and the temperate archaeal pleolipovirus SNJ2 originating from the halophilic archaeal *Natrialba* strain. The classical example of a temperate bacterial virus is the coliphage λ . Importantly, currently

available public sequence databases provide a significant culture-independent way to find new potential proviruses based on a homology search. However, the isolation of such viruses is still requires finding sensitive and cultivable hosts.

Progeny archaeal and bacterial viruses are released from host cells either by cell lysis at once or continuously through the cell envelope only causing host cell growth retardation (non-lytic life cycle) (Fig. 2). The difference between such virus exit strategies can be seen in synchronized one-step growth experiments by using high multiplicity of infections (MOI) to ensure that most of the cells are infected (Fig. 2(a) and (b)). In both cases by using optimized conditions, a high number of virus particles can be produced for certain virus systems. Production of prokaryotic viruses on solid media by using a double agar overlay plaque assay method is often more efficient than a liquid culture production method. However, some temperate viruses replicate poorly in liquid medium resulting in incomplete lysis, whereas some bacteria or archaea do not form lawns on solid culture media, and consequently the use of a plaque assay to determine the number of infectious viruses or solid media based virus production techniques cannot be used. Solid-media-based virus production systems are more effortless to set up and require typically less optimization than virus production in liquid medium. However, the liquid-medium-based growth systems are easier to scale up. Optimization of the culturing conditions for efficient virus production start from finding the optimal host for the virus and the optimal growth conditions for the host strain to support the maximal virus production. Several variables can be optimized for efficient virus production. Host cell growth, growth phase, cell density at the time of infection, MOI value, temperature, growth media composition, and optimal amount of the inducing agent are the major parameters to be optimized.

Purification of Viruses

Methods and techniques used for purification of bacterial and archaeal viruses are universal and applicable for eukaryotic viruses and other large macromolecular biocomplexes as well. The biophysical and biochemical properties of the virus particles such as size, shape, density, composition, homogeneity, net charge, hydrophobicity as well as sensitivity to shear, osmotic pressure, temperature, pH, and ionic strength affect the purification methods that can be applied (Fig. 3). For instance, enveloped viruses are more sensitive to shear-induced damage than are viruses having proteinaceous capsids. Filamentous particle morphology or the presence of long and fragile appendices e.g., spikes or tails, may make viruses sensitive to shear as well. Lipid components render viruses sensitive to organic solvents and detergents, whereas halophilic or thermophilic viruses living in acidic environments are often sensitive to low ionic strength or basic conditions.

Purification aims to remove impurities that originate from the host, culture media, and purification process itself. The heterogeneity of the produced virus particles (e.g., in size and/or density), the ratio of viruses to other sample components, the complexity of the starting material, and the initial concentration of viruses affect the purification methods that can be applied. In addition, the intended use of the virus specimen determines the needed quality, quantity, and concentration of the final purification product. In general, the more purification steps there are, the less the final yield will be and the higher the production cost. Luckily, many techniques are rapidly evolving in directions that require less sample. Typically, the initial purification steps aim to remove the most abundant impurities and to concentrate the sample to enable subsequent purification steps, where small sample volumes are beneficial, allowing higher throughput. Subsequent purification steps typically aim to remove the remaining impurities and to concentrate the sample.

Fig. 3 Different physico-chemical properties of virus particles and experimental conditions (blue, orange, and black) that have an influence on the selection of the purification methods (green). Depending on the virion properties, various chromatography methods can be combined with precipitations, ultrafiltration and ultracentrifugation methods to result in a highly concentrated virus specimen of high quality.

Whether the progeny virions are released by host cell lysis or in a non-lytic way e.g., budding (Fig. 2(c) and (d)) has an impact on the complexity of the starting material. Starting materials that result from viruses that are released from the cells without host lysis often have fewer impurities. In addition, the released viruses mostly represent intact mature functional viruses. In contrast, upon virus-induced cell lysis, mature viruses are released concomitantly with other cellular components including immature virus particles e.g., procapsids and other subassemblies. Thus, lysates are often more complex and heterogeneous starting materials for purification. However, archaeal and bacterial cells are devoid of cellular organelles which is an advantage when compared to the purification of eukaryotic viruses. Virus particles are generally relatively easy to separate from large-sized cellular debris and intact cells by high-speed centrifugation, microfiltration or a combination of these techniques. The biggest challenges in the purification arise from other macromolecular complexes having properties similar to the virus of interest. Selective removal of certain unwanted sample components at the beginning of the purification process typically improves separation in subsequent steps. For instance, the removal of contaminating nucleic acids (chromosomal DNA and ribosomal RNA) from lysates reduces the viscosity of the sample and dissolves complexes of nucleic acids and proteins. Large amounts of chromosomal DNA can hinder the use of precipitation methods as polyethylene glycol (PEG) precipitation in the presence of NaCl also efficiently precipitates DNA causing problems in the down-stream purification processes (see below). Addition of detergents usually increases the solubility, but may be detrimental for the integrity of membrane-containing and filamentous viruses. Importantly, the subsequent purification methods have to ensure that the added chemical components can be successfully removed if needed.

Ultrafiltration Methods

Ultrafiltration is an easy non-selective purification method, where separation is based on the size (Fig. 4). It requires no specialized equipment and little optimization and is thus rather inexpensive. Successful filtration purifies and concentrates the virus specimen. Filtration is driven by hydrostatic pressure that forces the liquid (buffer) and small sample components to pass through the semipermeable membrane. Separation capacity is determined by the pore size of the ultrafiltration membrane. Sample components larger than the pores are retained in the concentrate, whereas smaller components are transferred to the flow through (Fig. 4). Ultrafiltration is applicable to viruses that are smaller than ~100 nm in diameter. However, due to the size-based separation it cannot separate viruses from impurities that are larger than the pores of the ultrafiltration membrane that is used.

Ultrafiltration is a relatively fast purification method. Its speed depends on the pressure difference between the surface of the membrane and the flow through, and is affected by membrane porosity. Adsorption of the sample components to the membrane or blockage of the pores may slow down the filtration speed and result in low yields. Reduced permeability of the membrane can also increase the ion concentration and osmotic pressure of the concentrate that can be harmful for viruses. In such cases, testing different membrane materials and pore sizes, may improve the purification speed and yield.

The above described dead-end filtration, where the flow of the solution is perpendicular to the membrane surface, is the most typical filtration technique used. However, cross flow filtration (or tangential flow filtration) can also be applied. In cross-flow filtration the buffer flows parallel to the membrane surface reducing the accumulation of the sample components at the membrane surface and resulting in improved yields. Passive dialysis through membranes with specified pore sizes is also a valid and simple method to separate small and large sample components from each other. Importantly, filtration techniques are useful, if the buffer composition of the sample needs to be changed.

Precipitation Methods

Precipitations are simple to perform, require no specialized equipment, are inexpensive, and have generally good yields. Successful precipitation results in purification and concentration of the sample. The most commonly used precipitant for viruses is high

Fig. 4 Ultrafiltration. The pore size of the ultrafiltration membrane determines the size of components that are retained in the concentrate and those that are filtered through. Ultrafiltration speed is often enhanced by low speed centrifugation.

molecular weight polyethylene glycol (PEG 6000 or 8000) as it works for dilute and concentrated virus solutions, at variable pH (6–8 at least), and up to 2 M ionic strength. It is usually used in concentrations of 2–10% (w/v). Typically, virus-sized particles require lower concentrations of salt or polymer for their precipitation than small soluble proteins. Efficient PEG precipitation requires the presence of at least 0.5 M NaCl. Filamentous and helical viruses precipitate with lower PEG concentrations than the spherical ones. Importantly, PEG concentrations above 5% (w/v) precipitate cellular DNA, ribosomes, and vesicles. This needs to be taken into account of in the sample preparation before or after precipitation. Other polymers and salts such as ammonium sulfate can also be successfully utilized for virus precipitation. Concentration of the precipitating agent, time, and temperature affect the precipitation process. Sometimes step-wise precipitations with increasing amounts of the precipitant may improve purification. Precipitation as the first purification step is usually advantageous as it concentrates the virus preparation and removes several host-derived components.

Preparative Ultracentrifugation Methods

All particles gradually sediment downwards due to gravity. This process is slow for virus-sized particles and can be enhanced by using ultracentrifugation. Ultracentrifuges can accelerate an appropriate rotor up to the speed of 60,000–100,000 revolutions per minute (RPM), generating a relative centrifugal force (RCF) higher than $350,000 \times g$, where $1 \times g$ is equal to the force of gravity at the Earth's surface. Available techniques are analytical and preparative ultracentrifugation. Analytical ultracentrifugation is a powerful method for quantitative analysis of macromolecules in solution, whereas preparative ultracentrifugation is commonly used for purification of large biocomplexes, although it can also be used for certain analytical purposes. Preparative ultracentrifugation is highly selective and widely used for purification of viruses. The separation that can be achieved is based on the size, shape, mass, and density of the virus particles which determines the sedimentation coefficient specific for each virus. Obviously, the sedimentation speed is proportional to the applied relative centrifugal force. In general, larger sample components with higher masses sediment faster than the smaller ones. By using optimized protocols, the specimen obtained is typically pure, homogenous, and of high quality. Importantly, the same running conditions are usually suitable for viruses of similar sizes, densities, and morphologies. Filamentous material such as bacterial flagella and archaeal archaella, and extracellular vesicles are common impurities and challenges for virus purification by ultracentrifugation. Combining consecutive ultracentrifugation separation techniques (rate zonal and equilibrium) typically results in good recoveries and purities.

Two different preparative ultracentrifugation separation techniques can be distinguished: differential centrifugation and density gradient centrifugation (Fig. 5). Density gradient ultracentrifugation can be further divided into rate zonal and equilibrium (isopycnic) centrifugation. Differential ultracentrifugation is typically performed using fixed angle rotors (typical angles 15° to 45°), whereas rate zonal and equilibration centrifugation uses swing-out rotors (Fig. 5). The centrifugal force obtained during centrifugation depends on the rotor and more specifically on the distance between its center and the position of the sample components

Fig. 5 Different modes of preparative ultracentrifugation. (a) Separation in differential centrifugation is based on the size (diameter, mass) of the particles. (a, top) Fixed-angle rotors are typically used for this separation technique. (b) There are two different modes of density gradient centrifugation: rate zonal centrifugation and equilibrium centrifugation. Both separation techniques use density gradient solutions and the sample is typically loaded on top of the gradient material. In rate zonal centrifugation, particles move at different rates depending on their sedimentation coefficients. In equilibrium centrifugation, particles form zones at the position in the gradient that is equivalent to their buoyant density. (b, top) Swing-out rotors of different volumetric and maximal speed limits are available and typically used for density gradient centrifugation.

Fig. 6 Comparison of S-values of some bacteriophages (phiX174, PM2, phi6, and T4) to other cell components and some eukaryotic viruses.

in the tube during the run. Importantly, the centrifugal force is different along the length of the tube, being the highest at the bottom of the tube. This difference is compensated for by the use of density gradient solutions (see below). The volumetric capacity of a single ultracentrifuge rotor can be limiting. Thus, large-scale preparative approaches require several ultracentrifuges and rotors with high volume capacities. The use of preparative ultracentrifugation may be limited by the costs of ultracentrifuges and their rotors.

Differential centrifugation, i.e., pelleting, separates sample components based on their sedimentation rates and depends on the size, shape, density, the applied centrifugal force (speed), and the used medium (Fig. 5(a)). In general, large particles tend to pellet before small ones, dense particles sediment before light ones, and symmetrical particles (e.g., globular) sediment before the asymmetrical ones (e.g., particles with long extensions). Optimal conditions for pelleting always need to be experimentally verified. The sedimentation rate of a particle is its speed of travel in solution when subjected to a high gravitational force (g-force) upon centrifugation. The Svedberg unit (S) is a measure of this sedimentation rate. Typical S-values of prokaryotic viruses are in the range of 100 to 1000 S (Fig. 6), the larger the virus, the larger the S-value. During differential centrifugation, the sample components move towards the bottom of the tube as long as the force is applied. The separation power is rather limited due to the even dispersal of the sample components in the sample buffer before the run (Fig. 5(a)). Consequently, small sample components locating close to the bottom of the tube can pellet alongside large components. Thus, the formed pellets always represent an enrichment of different sizes of samples components – larger ones forming the majority. Sometimes step-wise removal of large sample components followed by repeated pelleting of the resulting supernatant containing the majority of small sample components with higher speed may result in a specimen with adequate purity. However, due to the limited separation power, differential centrifugation is often used as a final step to concentrate the viruses and transfer them to an appropriate buffer. Recovery yields are usually good, if the virus particles tolerate high shear forces. However, viruses can aggregate in high concentration solutions and resuspension of viruses from pellets can sometimes be difficult. Use of cushions (small volumes of high-density solution) might help to keep the particles in solution upon differential centrifugation and improve separation.

Density ultracentrifugation can be divided into rate zonal and equilibration centrifugation. Rate zonal and equilibrium centrifugations are among the few methods that enable the separation of particles that have the same size but different mass e.g., separation of the procapsids lacking the genome from the mature virions. They are performed by using continuous or step-wise gradients made of viscous solutions of various concentrations with the densities increasing towards the bottom of the tube. The gradients can be self-forming during the applied force (e.g., CsCl) or preformed (e.g., sucrose) before the ultracentrifugation. There are commercial gradient formers for making continuous gradients, but also continuous gradients can be formed by allowing a step-wise gradient to diffuse to linearity with time (e.g., overnight in a cold room). Selection of the gradient material depends on the density and other properties of the virus studied (Fig. 3). Importantly, the gradient must not affect the biological activity or stability of the virus. Whether ultracentrifugation results in good yields depends on the sensitivity of the viruses to the viscous and hyperosmotic nature of the gradient materials used, to high shear forces, and to the osmotic pressure present during centrifugation. Gradient materials that enable low viscosity gradient runs are also available. Sucrose is usually well-tolerated with viruses, but it enables experiments to be performed at densities up to 1.3 g/mL only, whereas dense salts such as CsCl can provide densities up to 1.9 g/mL. Other widely used gradient materials for viruses are glycerol and iodixanol. Some gradient materials such as CsCl may be toxic to cells, and this may hinder their application in virus purification. When working with CsCl, it is essential to ensure that the

applied forces are low enough so that CsCl is not precipitated at the bottom of the gradient during the run. The density of crystallized CsCl (4 g/mL) produces stress far in excess of the limits of the rotors causing serious safety risk. Manufacturers provide CsCl safety curves for all rotor types.

Upon density ultracentrifugation, virus particles are subjected to buoyant and sedimentation forces that are affected by the size, shape, mass, and density of the virus particles and the viscosity of the gradient material. They are separated and they form zones that are visible to the eye due to light-scattering under certain virus particle concentration thresholds (Fig. 5). In rate zonal ultracentrifugation, the density gradient is selected so that its highest density is lower than the density of the separated viruses allowing the separation of different components to occur according to their sedimentation coefficients. The viscosity of the gradient solution improves particle resolution as it prevents the broadening of the particle sedimentation zone by acting as a counterforce against the relative centrifugal force that is higher towards the bottom of the tube. Using an optimized combination of time and speed a powerful separation can be achieved.

In equilibrium ultracentrifugation, the density of the gradient must cover a wide range of densities allowing separation, and the maximum density must exceed that of the densest particle. Virus particles migrate until they reach the position in the gradient that is equivalent to their buoyant density and remain there forming a narrow concentrated zone. Thus, the applied equilibrium centrifugation time needs to be long enough to establish the equilibrium. The sample can be loaded either on the top of the gradient or on the bottom from where the sample components can reach their equilibrium positions by floating upwards (flotation centrifugation). When using self-forming gradient material (CsCl), the sample can be dissolved in CsCl and equilibrium positions will be achieved during the run simultaneously with the gradient formation. However, this approach is time consuming. Typically, the density gradient is selected allowing viruses to equilibrate at a position approximately two-thirds from the top of the gradient. Viruses are complexes of nucleic acid (DNA $\rho = 1.7$ g/mL; RNA $\rho = 1.8$ g/mL in CsCl) and protein ($\rho = 1.3$ g/mL in CsCl), and in some cases also lipids ($\rho < 1.0$ g/mL), and their buoyant densities usually range between 1.3–1.5 g/mL (in CsCl), the membrane-containing viruses typically having lighter buoyant densities.

Chromatographic Methods

Successful chromatography enables efficient but reversible binding of virus particles to a chromatography matrix and subsequent elution, in a controlled manner, results in a pure virus preparation with high biological activity separated from other sample components. In optimal conditions, chromatography offers high selectivity leading to good resolution, purity, and yield, accompanied by concentration of the sample.

Traditional chromatography columns are packed with porous particles and most of the adsorptive surface area resides inside the pores (usually ~50–100 nm in diameter). Binding of sample components to porous particles occurs mainly via diffusion. Although traditional matrixes can work for small-sized viruses, many viruses are too large to enter into the pores. Limited binding results in low dynamic binding capacity and reduced yields. Furthermore, due to the small diffusion coefficients of virus particles, low flow rates must be used to enable slow penetration and elution from the porous particles that can broaden peaks and lengthen the processing time. Virus particles are also subjected to shear due to eddy dispersion. However, traditional chromatography matrixes can sometimes be useful to separate virus-sized components in the void volume, while the smaller sample components are retained in the column.

There are non-conventional resins and matrixes available that enable purification of virus-sized complexes. Monoliths, for example, are made of a continuous single-piece stationary phase that has wide 1–5 μm interconnected channel networks distributed throughout the column. Sample components are transported in the column via convective mass transport in a laminar flow, and no diffusion is involved. Shear is minimal. All sample components have equal velocities irrespective of their size. Consequently, resolution and binding are independent of the flow rate, and immediate responses to changes in the mobile phase composition are obtained that result in narrow and sharp peaks. This enables the use of high flow rates promoting high processing speed. The channels have high surface area that is directly accessible for sample components. Consequently, efficient binding and high yields can be obtained and smaller columns and less buffer can be used for purification. Several bacteriophages with various morphologies have been successfully purified with monoliths (Fig. 7). Even though input samples have usually undergone some pre-purification steps, virus particles have also been successfully purified with monoliths directly from cell lysates.

Stacked membranes resemble monoliths in many aspects. They have large accessible channels and sample components are transported via convective mass transport that enables high dynamic binding and capacity. Thus, stacked membranes are applicable to purification of viruses, but as the bed height is usually lower than in monoliths, less sample can be purified.

Chromatographic methods where the separation is based on the charge, affinity, hydrophobic interaction, or size are applicable for viruses (Fig. 3). The surface properties of virions, the number and distribution of charge, the presence of hydrophobic spots, and their accessibility determine the type(s) of chromatography that can be applied. Importantly, binding of virus to the matrix can occur via multiple different contacts on the virion surface and can thus involve different chemistries depending on the pH and ionic strength. For instance, enveloped viruses have a negatively charged lipid bilayer that makes them potentially amenable for purification using anion exchange chromatography. In contrast, many halophilic viruses require high ionic strength for stability and their binding to ion exchange chromatography columns at low ionic strength is not possible. Virions that have exposed histidine, tryptophan, or cysteine residues, may be amenable to metal affinity chromatography that is based on their specific interaction with nickel, cobalt, or copper. Availability of specific antibodies enables affinity chromatography purification that is

Fig. 7 Virus purification by monolithic anion exchange chromatography with quaternary amine matrix. (a) Icosahedral internal membrane-containing PRD1 bacteriophages were first precipitated by PEG-NaCl from the lysate supernatant (input in b) and bound to monolithic column and eluted with a linear 0–1.5 M NaCl gradient (dashed line). Optical density (absorbance) is indicated by a solid line. Sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) analysis (Coomassie blue staining) of the peak fractions (marked by purple bars in a and b) collected during elution. The virus peak is indicated by an arrow head in a and b. Positions of the major PRD1 structural proteins are marked on the right. The figure is modified and reprinted from Oksanen, H.M., Domanska, A., Bamford, D.H., 2012. Monolithic ion exchange chromatographic methods for virus purification. *Virology* 434, 271–277. Copyright (2012), with permission from Elsevier.

based on the specific interaction between the antigen present on the virion surface and the antibody bound to the stationary phase. Size exclusion chromatography can work for small viruses. The optimal separation power needs to be established experimentally in conditions supporting the virus integrity. For instance, elution from ion exchange columns by increased ionic strength can be detrimental for some sensitive viruses, whereas elution due to change in pH can be damaging to others. Membrane-containing viruses are typically sensitive to buffers containing detergents. The composition of the elution buffer may also bring needs for additional purifications. Obtaining good separation requires optimization of the loading amount, eluent composition, and elution conditions (e.g., linear or step-wise gradients), as well as column chemistry. However, a single chromatography purification is usually fast to perform and can be easily scaled up by increasing the matrix amount and column size. Obviously, various chromatography methods can be tandemly applied to obtain better purity. Chromatography equipment, columns, as well as matrixes are relatively expensive, although columns and matrixes can be washed and reused.

Flow Field-Flow Fractionation Methods

Asymmetrical flow field-flow fractionation (AF4) is a method where sample components are separated based on their hydrodynamic sizes in the absence of a solid stationary phase (Fig. 8). Separation takes place in a thin channel of ~190–500 µm. The bottom of the channel (i.e., accumulation wall) is permeable and covered with an ultrafiltration membrane of selected material with defined molecular weight cut-off determining the size range of the sample components retained in the channel for separation. Separation is achieved by applying cross flow but is also influenced by the velocity of the channel flow that goes through the channel from the inlet to the outlet. Cross flow is perpendicular to the channel flow, and it pushes the sample components towards the accumulation wall. However, the sample components diffuse against the cross flow based on their diffusion coefficients. After equilibrium between the cross-flow force and diffusion is reached, the elution order of the sample components is dictated by their position in the channel and thus their access to different channel flow velocities that are the highest in the center of the channel and slowest at the walls (Fig. 8). Components having a diameter smaller than 0.5 µm are eluted in order with the small sample components eluting before the large ones.

AF4 is a gentle separation method since there is no stationary phase. As separation is based on hydrodynamic size, the same methods and running parameters can be applied to various viruses of similar sizes. However, optimization of the flow rates, gradients, eluent composition, and loading amounts is required for the best separation. AF4 was originally designed for analytics rather than preparative applications, and thus the loading amounts that still lead to good separation are relatively low. Despite this limitation, several viruses have been successfully purified by AF4, establishing it as one of the potential virus purification methods.

Fig. 8 Principles of AF4 fractionation. Applied cross flow pushes the sample components towards the accumulation wall that consists of an ultrafiltration membrane and a permeable ceramic frit through which the cross flow is pumped out. Sample components that are smaller than the pores of the ultrafiltration membrane pass through (green spots). Remaining sample components diffuse against the cross-flow force depending on their diffusion coefficients. Channel-flow rate is slowed down at the channel walls due to friction and the eluent moves with the highest pace in the middle of the channel. Consequently, smaller sample components with higher diffusivity reach higher flow rates and elute first. Viruses, proteins, and channel height are not to scale. In practice, the sample components occupy only $\sim 1\%$ of the channel thickness. Separation can be coupled to on-line detectors such as UV, multi angle light scattering (MALS), dynamic light scattering (DLS), fluorescence etc. to obtain information for instance on particle concentration, size and size distribution. Fractions can also be collected for off-line analysis.

The running time for a single AF4 experiment is typically short, less than one hour. Consequently, several experiments can be performed in a row to improve the total yield. Recovery yields are generally good, and the integrity and infectivity of viruses is well maintained. AF4 can be coupled to multiple detectors (Fig. 8) that enable simultaneous collection of data on for instance the size and size distribution of the viruses. AF4 is broadly compatible with a variety of buffers. It has been successfully utilized for purification of archaeal viruses in buffers containing moderate (0.6 M) and high (1.6 M) total ionic strengths. Initial investment costs for AF4 are high and the theory is rather complicated.

Assessing Purification Performance

Plaque assay is an extremely sensitive and easy method to determine the number of infectious viruses (plaque forming units, pfu) and hence the success of the purification of infectious viruses. However, not all virus systems produce plaques and the efficiency of the plating (EOP) can be very low. Protein concentration can be estimated by multiple methods (for example the Lawry method or Bradford assay) that depend on the amino acid composition of the proteins and vary in their sensitivity as well as compatibility to various chemicals. The easiest and most sensitive method to estimate the amount of protein is based on absorbance at 280 nm (A_{280}). Additional absorbance measurement at other wavelengths such as 260 nm (A_{260}) provides further information about the nucleic acid content. Depending on the ratio of protein and nucleic acid as well as the amino acid and nucleotide composition, each virus has a typical A_{260} to A_{280} ratio. Based on the infectivity and protein concentration or absorbance values, specific infectivity of the virus preparation (pfu/mg of protein; pfu/one A_{280} unit; pfu/one A_{260} unit) throughout the purification can be calculated and compared. Each virus has its own optimal specific infectivity value which is dependent on the EOP for the host used, and on the size and composition of the virus. In one virus system or between similar virus systems specific infectivity is a good indicator of the quality of the virus preparation. A high ratio between the number of infectious viruses and quantity of protein indicates a high-quality specimen. As an example, purified bacteriophage PRD1 has specific infectivity values over 10^{13} pfu/mg of protein (Fig. 9(b)).

Denaturing sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) is commonly used to analyze the quality and composition of the purified virus sample. The protein composition can be visualized by staining the gels with protein-specific stains such as Coomassie blue (Fig. 9(a)). The presence of lipids can be detected from the SDS-PAGE gels by lipid-specific stains, but more detailed information on the viral lipid composition can be obtained by lipid extraction followed by thin layer chromatography or lipidomics. The presence of nucleic acids can be visualized in the stacking gels of SDS-PAGE gels, but agarose gels coupled with nucleic acid specific stains and nucleic acid specific techniques and sequencing are required for obtaining information on the viral genome. Transmission electron microscopy (TEM) and negative staining is one way to analyze the purity of the samples, but it also gives information on virus morphology and can be used to enumerate viruses especially when a plaque assay cannot be applied. The specimen preparation for cryo-EM results in the preservation of biological specimens at near native conditions within a thin amorphous ice film allowing more detailed analysis of the virus morphology and sample purity, and potentially an atomic resolution structure of the virus particles (Fig. 9(c)).

Fig. 9 PRD1 virus purification by precipitation, density gradient ultracentrifugation in sucrose and concentration by differential centrifugation. (a) SDS-PAGE analysis followed by Coomassie blue staining of different purification stages of bacteriophage PRD1: (I) production as a lysate; (II) PEG-NaCl precipitate of the virus; (III) purified virus after 5%–20% rate zonal sucrose gradient and differential ultracentrifugation; (IV) purified virus after 5%–20% rate zonal and 20%–70% equilibrium ultracentrifugations followed by differential ultracentrifugation. Molecular mass marker is from 10 kDa to 100 kDa. The PRD1 major capsid protein P3 with the highest copy number in the virion is 43 kDa. (b) Purification statistics derived from purification of 1 litre of lysate. See the explanations for I–IV. (c) Cryo-electron microscopy micrograph of bacteriophage PRD1 purified by PEG-NaCl precipitation, rate zonal and equilibrium ultracentrifugation in sucrose, and concentrated by differential centrifugation (see IV in a and b). Conclusions

More than 100 years have passed since the isolation of the first bacteriophage. Archaeal viruses were recognized over 60 years later at the time when archaea were discovered and acknowledged as the third domain of life. Bacteriophages and archaeal viruses are the most abundant group of biological entities on Earth, outnumbering their host cells by at least ten-fold thus influencing global biogeochemical cycles and driving microbial evolution. These parasites thrive in various ecological niches all over the world. Since their discovery, bacterial and archaeal viruses have served as model systems to unravel the fundamental aspects of virology, microbiology, structural biology, and ecology. Methods and technologies that provide a high number of viruses and virus-like particles purified to homogeneity are required not only for basic research but also applications of viruses in biotechnology, medicine and industry. Success in obtaining high quality samples in quantities relies on the ability to produce high titer virus stocks and is largely dependent on the particular virus and its host cell. There are certain principles and methods that can be broadly applied, but experimentation of the optimal storage, production, and buffer conditions for each virus of interest is typically needed to maximize the yield. Virus purification techniques involve filtration, dialysis, precipitation, ultracentrifugation, chromatographic and flow field-flow fractionation methods that are optimized and used together and sequentially in different combinations. There is a growing need for new virus purification technologies to meet the purity criteria for phage and virus-based gene therapy, vaccine developments and nanotechnology, paving the way for new innovations and applications.

Glossary

Nanopore sequencing A technology of single molecule sequencing enabling direct and real-time sequencing of DNA and RNA strands using nanopores (either biological or solid state).

Next generation sequencing/High throughput sequencing New methods for high speed, low cost sequencing of genomes, inclusive of both second and third generation sequencing technologies.

Second generation sequencing Second generation methods are all characterized by the requirement to prepare amplified sequencing libraries before the process of sequencing of amplified DNA clones.

Sequencing library Any piece of nucleic acid that is attached to adapter barcodes for sequencing. Libraries may

also contain indices enabling the multiplexing of libraries from different samples on the same sequencing run.

Shotgun sequencing A technique for determining the sequence of entire genomes based on sequencing of random fragments of DNA that are then assembled by *de novo* assembly into fragments.

Single cell sequencing The sequencing of information e.g., transcriptome, at the level of individual cells.

Single molecule sequencing Techniques that can read the base sequence directly from individual strands of DNA or RNA present in the sample of interest, without the requirement for amplification.

Introduction

Over the last two decades, significant progress has been made in the field of DNA sequencing. Sanger (dideoxy) sequencing, or what may be thought of as traditional sequencing, has been around for more than 40 years. This platform produces well-trusted, up to 1-kbp long reads which are still considered the gold standard for sequencing and are routinely used for clinical gene tests or validations, although their low throughput limits them to single or small batches of targets. Next generation sequencing technologies however offer a significant step forward in our capability to dissect virus-host interactions and explore the viral evolutionary mechanisms that underpin transmission and pathogenicity. The diversification of these new technologies have enabled the diagnostic evaluation of gene panels, whole genome sequences and viral transcriptomics analysis, which have become commonplace within the scientific literature (Fig. 1). Importantly, such new chemistries have enabled a dramatic reduction in cost per gigabase, thereby increasing the potential for sample throughput. All of this has had a significant impact upon the field of virology.

First Sequencing Methods

The first short DNA sequences were obtained in the early 1970s using a variety of different methods. However, in 1977, three new sequencing methods were published; (1) Allan Maxam and Walter Gilbert, working at Harvard University, published a DNA sequencing method based on chemical modification of DNA and subsequent cleavage at specific bases. Also known as chemical sequencing, this method allowed purified samples of double-stranded DNA to be directly sequenced. Maxam-Gilbert sequencing requires radioactive labeling at one 5' end of the DNA and purification of the DNA fragment to be sequenced. Chemical treatment then generates breaks at a small proportion of one or two of the four nucleotide bases in each of four reactions (G, A + G, C, C + T) generating a series of fragments, from the radiolabelled end to the first "cut" site in each molecule. The fragments in the four reactions are electrophoresed side by side in denaturing acrylamide gels for size separation and thus determination of the base sequence; (2) a method for the direct determination of RNA sequences, based on digestion of radiolabelled RNA with different ribonucleases, was developed by George Brownlee and co-workers at Cambridge University, UK; (3) Fred Sanger and co-workers (Cambridge, UK) published the chain-termination method which used fewer toxic chemicals and lower amounts of radioactivity than the Maxam-Gilbert method. Separate reactions are set up, each with a small amount of one of the four (A,T,G,C) dideoxynucleotides and larger amounts of deoxynucleotides. The reactions produce chains complementary to the DNA to be sequenced, until extension is terminated by incorporation of a dideoxynucleotide, producing fragments which are analyzed by electrophoresis. Sanger sequencing has been applied to RNA using a reverse transcriptase to generate cDNA fragments, or DNA using a DNA polymerase and was flexible in that it could incorporate either a radiolabelled oligonucleotide primer or a radiolabelled deoxynucleotide. Due of its comparative ease, the Sanger method was soon automated and was the method used in the first generation of DNA sequencers. Sanger sequencing is the method which prevailed from the 1980s until the mid-2000s. Over that period, great advances were made in the technique, such as fluorescent labeling, capillary electrophoresis, and general automation. These developments allowed much more efficient sequencing, leading to lower costs. The Sanger method is the technology which produced the first human genome in 2001, ushering in the age of genomics. The first two methods have been used to sequence the

Fig. 1 Comparison of advantages of different types of enrichment and high throughput sequencing library preparation methodologies. (A) *Sanger sequencing*: A low throughput methodology where reads are sequenced that match the consensus level sequence of populations within the sample. (B) *Shotgun sequencing*: A protocol, with minimal intervention and biases, that sequences all dsDNA templates present within a sample (either native or converted from RNA using reverse transcription). (C) *Amplicon sequencing*: A targeting and enrichment protocol that directly targets specific regions with gene specific primers and enriches via amplification. Incurs biases associated with amplification, but generally produces deep coverage across targeted regions. (D) *Third generation (long-read) sequencing*: Produced using single molecule sequencing by either Single Molecule Real-Time (SMRT) based platforms (including Pacific Biosystems) or by use of synthetic nanopores (presently available platforms include Oxford Nanopore technologies). Results in single long reads representative of the original template. (E) *Metagenomics*: Employs shotgun sequencing or RNA-Seq protocols to characterise all species of pathogen present within populations. (F) *Synthetic long/linked reads*: A methodology able to tag reads originating from the same template with specific unique molecular identifiers denoting the original template from which they originated. After sequencing, these indexed short reads sharing unique indices can be combined to produce long reads. (G) *Probe hybridization enrichment*: Probes can be used to enrich for nucleic acids derived from viral material either directly after nucleic acid extraction (prior to library preparation) or after the amplification stage of library preparation. The homology of the probes to the pathogen is key to the success of the method.

unusually long (~80–250 residues) poly(C) tracts of foot-and-mouth disease virus (family *Picornaviridae*, genus *Aphthovirus*) and encephalomyocarditis virus (family *Picornaviridae*, genus *Cardiovirus*), a feat which Sanger sequencing is unable to achieve.

Next Generation Sequencing and Applications in Virology

All second-generation sequencing technologies utilize chemistries incorporating an amplification step prior to the actual process of sequencing, resulting in millions of short clonal copies of each sequencing library being produced, which are then sequenced in massive parallel sequencing reactions. Although there are distinct differences in the way second generation sequencing libraries are produced between platform chemistries, essentially a sequencing library is a short piece of DNA (typically between 50 and 600 bp in length) generated from a sample of interest. This is bracketed by platform-specific barcodes or adapter sequences, and unique barcodes enabling multiple samples to be combined (multiplexed) on the same sequencing run. Any template lacking appropriate adapter sequences would not be recognized as a library. The four main second generation sequencing platforms i.e., 454, Illumina, Ion torrent and SOLiD, all employ short reads (< 600 bp) and share an amplification stage prior to sequencing to drive their chemistries.

454 (Pyrosequencing)

Originally marketed by 454 Life Sciences (now owned by Roche), 454 was the first commercial HTS platform released in 2005 and acted as one of the foundational platforms of the technology, however, the chemistry was discontinued in 2013. The 454 technology uses the sequencing by synthesis chemistry in which DNA molecules are sequenced upon the addition of individual nucleotides. Initially, DNA molecules are attached to nanobeads in an emulsion of oil and PCR reagents. An excess of beads favors the statistical probability that there should be at least a single bead for each nucleic acid template and the emulsion leads to a formation of droplets, each containing a bead, ssDNA template and PCR reagents. Each reaction generates multiple ssDNA clones of an original template DNA present within the droplet enriching clonal copies on the surface of the nanobeads. Once the droplets are broken the ssDNA-coated beads within the droplet are released and dispersed into nanowells across the surface of a microtiter plate. Each well contains a single bead, in addition to luciferase and sulfurylase molecules. As nucleotides are washed across the plate a single unlabeled nucleotide at a time. Each time a nucleotide matches the dNTP in the cloned template, the base is added to the DNA

chain, releasing a pyrophosphate. The sulfurylase processes the pyrophosphate, creating available ATP, which is processed by luciferase to generate a pulse of light. Higher error rates for such datasets arise from homopolymeric regions and artificial amplification artefacts. 454 was discontinued by Roche in 2013. Ion-torrent (marketed by Thermo/Life Technologies) utilizes a similar chemistry to the 454 system with emulsion PCR as a central part of the library preparation, however, it has important differences in its sequencing reaction, which is detected by a pH semiconductor rather than fluorescence, with the release of protons during nucleotide incorporation being detected using an ion sensor to measure shifts in pH through changes in conductance. Ion torrent can use different sized chips for sequencing, which adds flexibility to the maximum read numbers produced during each sequencing run, e.g., a run requiring a larger number of reads or an increased number of samples would require a higher specification chip.

SOLiD sequencing developed by Applied Biosystems shares similar elements of the 454 library preparation in which DNA is fragmented onto beads in an emulsion PCR, however the sequencing centers around the principle of ligating of di-basic probes to a complementary template resulting in fluorescence.

Illumina Sequencing

Illumina sequencing utilizes an alternative method of on-board amplification called “bridge amplification”. As with other short read chemistries, libraries are composed of short fragments of the dsDNA of interest, with adapters and indices attached to either end. Libraries are dispersed across the flow cell surface and allowed to bind to a lawn of primers. Once bound to the flow cell, libraries undergo “bridge amplification”, whereby clusters of clonal copies of each original library are produced. These clusters of libraries are then sequenced using a process whereby reversible terminators incorporated into fluorescently labeled nucleotides added at each step block elongation after incorporation of a single nucleotide, in a process analogous to Sanger sequencing. Any incorporated nucleotides are then detected by a colored light emission, before denaturation solutions remove the reversible terminator, enabling elongation and attachment of the next fluorescently labeled/blocked nucleotide. Illumina have a number of different models of sequencer available from small benchtop machines including the iSeq-100, MiniSeq and MiSeq, to the larger scale machines (HiSeq 4000, HiSeq X and NovaSeq). Newer versions of the technology including the iSeq, MiniSeq NextSeq use reduced numbers of colors to streamline chemistries and reagents, combined with patterned flow cells to increase sequencing accuracy.

It has been the introduction of the benchtop level machines to the market that has driven the genomics revolution, enabling access to the platforms which had previously not been accessible due to the high upfront costs for such technologies.

Applications of High-Throughput Sequencing in Virology

The high throughput sequencing of viruses produces a snapshot of the total diversity within a virus population, below the level of consensus that is possible by Sanger sequencing. This is particularly useful when investigating RNA viruses, which due to an error prone RNA-dependent RNA polymerase produce large populations of progeny virions which differ from the parental virus. Such diversity can be characterized by the assembling of sequencing reads and characterization of polymorphisms in the assembled contigs (constructs of overlapping reads). During the analysis, the greater the number of reads mapped to each position (known as coverage depth), the higher the accuracy or level of confidence in the conclusions that can be drawn from data. This will proportion confidence to predictions made from the data regarding minority variants that are truly present within the population, as opposed to artefacts of library preparation or analysis. Genome sequencing can also be taken as consensus (present in more than 50%) of reads at a given position. These principles underlie how workflows such as metagenomics, PCR amplicon sequencing and enrichment strategies can be successfully tailored to specific applications.

Approaches to high throughput sequencing (HTS) in virology, generally take one of three main approaches. The term “metagenomics” describes all processes by which sequences can be identified without any prior knowledge. This is most useful in studies where virus discovery, or the characterization of different types of virus e.g., characterising the virome within a sample, are the main objectives. DNA sequencing or amplicon sequencing describes the enrichment of a sample using amplification (mainly PCR), providing ultra-deep coverage datasets on targeted parts of a viral genome in order to identify minority variants involved in drug resistance, transmission or virulence studies. Finally, the targeted enrichment of libraries during library preparation describes the specific enrichment of viral nucleic acid in order to increase the number of virally derived reads after sequencing thereby reducing host background and increasing overall specificity. Such protocols are particularly relevant in clinical samples where the amount of virus may be limited, but the identity of the virus known. Although enrichment for viral reads will reduce background read counts and increase sensitivity for viral reads in hard to sequence samples, this comes at an increased cost in terms of reagents and labor.

Metagenomic Approaches

The term metagenomics can be defined as the characterization of genetic information directly from the clinical or environmental sample in the absence of culture. Metagenomic approaches have been used extensively for pathogen discovery and the characterization of microbial diversity within samples and thus constitute some of the most widely used applications of high throughput sequencing in virology. Whilst the workflow presents considerable flexibility in tailoring to the objectives of any screening study, it is particularly effective in characterising unknown pathogens without a priori knowledge of genomes, or when identifying multiple virus types within samples, e.g., virome analysis.

In such studies, total DNA/RNA is extracted from samples, libraries prepared and sequenced by either shotgun sequencing or RNA sequencing protocols. Metagenomic workflows have the additional benefit of being effective when nothing is known about the pathogens present in the sample, thereby circumventing the need for expensive primers or probes which makes it particularly useful when dealing with outbreak situations, as demonstrated recently during the Zika virus (genus *Flavivirus*, family *Flaviviridae*) outbreak, where the causative virus was previously unsuspected. Whilst the use of metagenomics to produce viral whole genome sequences from outbreak samples can provide an enhanced level of resolution, the overall sensitivity of such protocols is significantly less than more targeted methods. However, metagenomic approaches have been used effectively in previous studies of outbreaks of norovirus (genus *Norovirus*, family *Caliciviridae*) and parainfluenza virus (genus *Respirovirus*, family *Paramyxoviridae*), enabling tracing of transmission in real-time. Such information can be invaluable in front line healthcare settings, particularly when identifying transmission clusters between patients and clinical staff. Metagenomic protocols have the added advantage of being able to generate both host and viral derived data, thus potentially informing on virus associated cancer formation and diversity of integrated virus genomes, which can provide an important additional level of detail to tailored treatment programs in patients.

Whilst shotgun metagenomic protocols provide a representation of nucleic acid present within a sample, its sensitivity is limited. It can be further enriched by incorporating random amplification of nucleic acid whether using Sequence Independent Single Primer Amplification (SISPA), Single Primer Isothermal Amplification (SPIA) or using RNA-Seq protocols to probe samples for viral transcripts, although these introduce their own biases. The application of enrichment protocols to these approaches, although useful can result in costs becoming prohibitively high. Random priming and metagenomics workflows have previously produced genome sequences for a novel mink astrovirus (genus *Mamastrovirus*, family *Astroviridae*), paramyxoviruses (family *Paramyxoviridae*), influenza viruses (family *Orthomyxoviridae*), dengue virus (genus *Flavivirus*, family *Flaviviridae*) in infected mosquitos, viruses in stool and avian viruses. SISPA is one of the more commonly employed protocols for metagenomics investigations, particularly virus discovery and involves the DNase digesting a sample to reduce host nucleic acid, in order to specifically enrich for viral RNA before an amplification step with tagged primers. SISPA was used to identify the Schmallerberg virus where a small number of reads led to the identification of a novel virus (Schmallerberg virus; genus *Orthobunyavirus*, family *Peribunyaviridae*) infecting dairy cattle. Although RNA-Seq based protocols are effective in identifying the presence of RNA viruses in samples, it should be underlined that the technical and analytical requirements for transcriptomics studies are very different to those requirements in metagenomics studies. The downside of such protocols is the large percentages of reads deriving from either host or other organisms present in or contaminating the sample. As a result, the read depth is often variable, with the reagent cost high. Other applications include RNA-Seq-based approaches in which data can be used to identify extraneous viral reads in those unmapped reads after host depletion. Examples of previous application of such datasets include the detection of adventitious agents within vaccine seed stocks or the detection of viral contaminants in bioreactor cultures. Virome and microbiome diversity are also areas where metagenomics has provided significant contributions to our understanding of viruses within our environment with investigations of the RNA virosphere within samples taken from several locations including the Mediterranean and underground lakes on the Western Antarctic peninsula.

RNA Sequencing

More traditional applications for RNA sequencing in virology (i.e., outside of metagenomics) include small whole genome sequencing and transcriptomic profiling, from differential gene expression (poly-A enriched) to mapping sites of transcript initiation (Cap analysis gene expression sequencing - CAGE-Seq). Many viral infections suppress host cell expression, resulting in the sequencing of viral mRNAs which are instead produced by the hijacked cellular machinery. The inclusion of enrichment protocols such as ribosomal depletion (for total RNA-Seq), enable the sequencing of non-polyA species of RNAs such as non-coding regions, whereas enrichment of poly-A for differential gene expression studies would reveal the impact of viral infection upon cellular expression. RNA-Seq is particularly powerful for investigating host-pathogen interactions and has been used to characterise host transcriptional responses to Ebola virus, identify interactions between hepatitis virus associated hepatocellular carcinoma and investigate virus infected plant transcriptome profiles.

The development of advanced RNA sequencing methodologies in recent years has made it possible to monitor viral gene expression at single nucleotide resolution. Protocols for the sequencing of total RNA (RNA-Seq) and ribosome-protected RNA fragments (RPFs) (Ribo-Seq, also known as ribosome profiling) of hepatitis C virus (HCV; genus *Hepacivirus*, family *Flaviviridae*), influenza, Epstein-Barr virus (EBV) and murine leukemia virus (MuLV; genus *Gammaretrovirus*, family *Retroviridae*) have been established. Other advanced RNA-Seq processes including ATAC-Seq and DIVA-Seq that investigate chromatin accessibility for vRNA have also been performed in human immunodeficiency virus (HIV; genus *Lentivirus*, family *Retroviridae*) and herpes simplex virus (HSV; genus *Simplexvirus*, family *Herpesviridae*) infections, respectively, enabling the identification of transcriptionally active regions of viral and cellular nucleic acids.

Due to their level of sensitivity, contamination can be an issue with RNA-Seq-based protocols, with results and analysis needing to be taken in the context of the nature of the sample and library preparation.

DNA Sequencing – Amplicon Sequencing

If the pathogen's identity is known prior to testing or the whole genome is not required, a more suitable and cost-effective approach may be to enrich for an informative part of the viral genome prior to sequencing, using amplification with primers complementary to

known nucleotide sequences within that region. This is a common approach for enriching small viral genomes although the use of PCR introduces certain well-established biases into the resultant data sets. In many clinical settings whole genome sequencing may not be feasible, whilst targeted sequencing techniques of specific regions of the virus e.g., non-structural genes, provides an alternative that has been employed to identify variants involved in disease pathogenesis and prognosis.

Several different PCR techniques can be applied, including long-range PCR, multiplex PCR and microdroplet-based PCR. Multiplex PCR for NGS can include the parallel amplification of large numbers of targets simultaneously as in AmpliSeq or microdroplet-based PCR as used as part of the RainDance platform. Long-range PCR can facilitate the sequencing of entire genes or even genomes with primers generating amplicons with an average length of 10 kb. Examples of PCR amplified approaches to whole viral genome sequencing have been reported for influenza virus, HCV, equine infectious anemia virus (genus *Lentivirus*, family *Retroviridae*), dengue virus and porcine reproductive and respiratory syndrome virus – PRRSV (genus *Betaarterivirus*, family *Arteriviridae*). The advantage here is that sequencing of amplicons will result in a sequence reads being highly specific for the chosen amplicons (high specificity) and with even coverage across the amplicon (dependent upon the nucleotide sequence). The variability of some viruses, including HCV, has necessitated the use of overlapping primer sets in order to capture total sequence heterogeneity. Influenza virus sequencing protocols have used PCR enrichment, as multiple genome segments can be amplified using conserved primers.

Often specific gene panels or hotspot mutation panels can be used when working with multiple targets such as HIV drug resistance genes or can enable the characterization of tumor associated viruses, in parallel with the mutational profiles of their associated tumors as has been used with human papillomavirus (HPV; family *Papillomaviridae*) and human herpesvirus 8 (HHV8; Kaposi's sarcoma-associated virus; genus *Rhadinovirus*; family *Herpesviridae*). This can contribute important information for patient screening and tailoring treatment regimes. Such panels are useful in institutions that process large numbers of samples and offer more efficient and cost-effective approaches to testing. Few comparative studies have been performed using different methods to sequence the same material. One study compared to the performance of different sequencing methods using HCV infected patient material and spiked in-vitro transcripts in serum. Compared to other protocols (including metagenomics, RNA-Seq and enrichment), amplicon sequencing generated greater sequence depth and increased sensitivity, particularly in low viral load samples. PCR amplification can also be useful when working with samples with degraded nucleic acid, often found in DNA extracted from formalin-fixed paraffin-embedded (FFPE) samples. PCR amplification also has its disadvantages, due to its very nature, i.e., amplification. The inclusion of amplification in the library preparation is particularly important when considering SNPs and minority variants as it can result in preferential amplification of specific variants or sequences, resulting in a loss of diversity for those variants that may not be amplified as efficiently. It can also lead to the occurrence of jackpot mutations, which are introduced in early amplification cycles and become dominant in the later cycles as they are carried forward (and therefore indistinguishable from the true viral sequences). Issues with primer bias in primer regions should also not be discounted.

Enrichment Strategies

The purpose of enrichment is to use a selective method to increase the ratio of virus sequences to non-virus sequences, or to reduce the frequency of non-viral sequences, maximizing the number of viral reads to be sequenced, while remaining unbiased towards the natural composition of the genome. This results in an increased specificity of sequencing, whilst eliminating the need for additional culture or amplification, however, it is dependent upon homogeneity between the target and probe/primer regions. Target enrichment is often used with clinical samples and can produce increased genome coverage from limited clinical samples in an economic way, with methods involving the use of DNA or RNA probes, which are potentially overlapping and complementary to the pathogen reference sequence. Unlike PCR, these processes can be performed in a single tube format containing overlapping probes covering the entire genome. In hybridization, such probes are bound to a solid phase and, as in enrichment of rotavirus, can be performed in a streptavidin coated ELISA plate, whereas probes can also be added in liquid phase and be bound later. Success, however, is based on both the a priori knowledge of the viral genome sequence/reference or conserved nature of the viral genomes.

Positive Selection-Based Enrichment

Positive selection-based capture enriches samples for viruses using PCR, microarray or virus capture (in solution-based hybridization), binding and retaining the viral reads within the sample. Poly (A) enrichment is one of the more commonly used modes of positive selection for viruses, with commercial kits readily available. Sequence specific enrichment probes have been used previously to study the human virome with VirCapSeq and VirCap and viroFIND. Although resulting in increased virus derived read numbers, both were limited in the identification of highly divergent viruses. Such probe capture systems have also been used to improve sequencing of viral sequences from FFPE tissue samples resulting in up to 37,000-fold coverage of regions covered by probes. Such probe-based strategies have proven useful in the characterization of enteric viruses in sewage, compared to metagenomic based strategies where viral concentrations were low, paired with high sample complexity. Adapted protocols have employed multiplexing steps to enable high throughput sequencing of such samples on the MinION and Illumina platforms.

Negative Selection-Based Enrichment

Negative selection approaches include ribosomal depletion and involve the binding and removal of non-viral reads from the sample. In addition to being used in gene differential expression protocols, ribosomal depletion has been used to sequence several

viruses including HHV8, GB virus C (genus *Pegivirus*, family *Flaviviridae*) and transfusion transmitted (or torque teno) virus (TTV; genus *Alphatorquevirus*, family *Anelloviridae*).

Single Cell Sequencing

Since their introduction in 2009, single cell sequencing technologies have presented a step forward in the capability to investigate virus-host interactions, with the majority of studies focussing on expression profiling in infected vs non-infected cells. This usage hints at its real potential to dissect the complex relationships between host and virus at the level of individual cells or pathogens. Several alternate approaches have been developed, based on cells sorted either by fluorescence-activated cell sorting (FACS) or using droplet-based workflows. These include Smart-Seq and SmartSeq2 for processing FACS-sorted cells and Drop-Seq, inDrop and 10X Genomics Chromium for droplet-based technologies. Droplet-based methods have advantages including increased throughput and reduced reagent costs, but frequently require more specialist equipment to place nucleic acids and reagents inside droplets.

Viruses are dependent on the host cell to replicate and thus heterogeneity in the host cell population will be a significant factor in viral infection outcome. Achieving and maintaining a 100% infection rate of cells is a challenging task for an infecting virus, due to; (1) cellular heterogeneity – different stages of the cell cycle, different states of cell activation or different subsets of cell, and (2) heterogeneity in the virus particles. Single cell technologies can dissect out these heterogeneities and their impact upon the outcome of infection. Such experimental strategies, however, are not without their challenges, with three of the most significant being; (1) the ability to isolate cells in an appropriate way; (2) the ability to generate comprehensive sequence data from minute amounts of nucleic acid; and (3) how to discriminate between true variation and background noise.

Using Single Cell Sequencing to Investigate Cellular Heterogeneity and its Impact on Viral Infection

Single cell sequencing of viruses has predominantly focussed upon establishing cell to cell variability or cellular heterogeneity and its impact upon viral infection rates. Whilst early studies used fluorescently sorted cells and time lapse microscopy to establish the presence and expression of virus encoded reporter genes, more recent investigations have employed molecular methods including high throughput sequencing protocols to establish cellular expression. Studies of the impact of cellular heterogeneity upon viral infection and outcome have predominantly focussed upon differences in susceptibility to viral infection. Such studies have explored the permissiveness of mouse T cells and human macrophages to human influenza A virus (genus *Alphainfluenzavirus*) infection, identified cellular marker subsets associated with susceptibility to HIV-1 infection and characterized genes associated with latent HIV-1 infection, cell cycle status and transcriptional heterogeneity. These technologies have also been used to study the impact of immune gene expression upon viral infection for HCV, vesicular stomatitis virus (VSV; genus *Vesiculovirus*, family *Rhabdoviridae*) and West Nile virus (genus *Flavivirus*, family *Flaviviridae*). The impact of flavivirus vaccination upon the host transcriptome, notably focussing upon cellular immunity has also been explored. Of note, is a study that investigated cellular heterogeneity of dendritic cell subsets taken from elite controller patients, previously described to have more efficient immune responses to HIV-1 infection. Single cell analysis enabled researchers to characterise markers in a subset of dendritic cells with an improved capability for T cell proliferation. The utilization of a dual RNA-Seq approach in single cells, thereby characterising both host cell and virus expression during HSV-1 infection looked at how the antiviral state in infected cells was reset after virus infection. The study concluded that whilst most cells were able to establish an antiviral state, HSV-1 was able to induce cellular reprogramming in a small number of highly infected cells causing them to revert to embryonic transcriptional states, effectively resetting the cells transcriptome. The elucidation of such novel mechanisms makes single cell sequencing a powerful technique for defining and understanding underlying key events that occur within a cell during viral infection.

Using Single Cell Sequencing to Investigate Viral Heterogeneity

The impact of viral diversity upon the outcome of cell infection has also been the focus of studies, characterising the level of viral diversity within single infected cells during infection. For example the impact of viral diversity upon drug resistance markers during HCV replicon infection was investigated, revealing up to 113 copies of RNA derived from a single HCV replicon present within a single infected cell. Other studies include VSV, FMDV, HIV-1 and Influenza and their impact upon cells during infection, in addition to investigating the role of defective interfering particles (DIPs) in generating diversity during infection and the impact they have upon productive infections of cells.

Two principles are becoming clear from this research which will influence how the field develops – (1) increasingly, evidence suggests that for several viral infections, multiple copies of vRNA from the same virus within single infected cells maintain pools of diversity for subsequent transmission; and (2) there exists a role for transcriptionally distinct cell clusters in response to virus infections. It is possible that these types of study will be able to answer more fundamental questions regarding viral infection, such as identifying molecular switches between lytic and latent infection types.

Single Molecule Sequencing (Pacific Biosciences and Nanopore)

One of the main limitations with short read sequencing (SRS) platforms comes from the requirement for amplification of individual libraries prior to sequencing. This can preferentially amplify specific sequence motifs, resulting in an underrepresentation of bases in

areas of high or low GC content. Amplification can also result in a loss of data concerning RNA and DNA modifications which can convey a significant amount of information regarding the *epi*-transcriptome. Furthermore, during early cycles of amplification, base incorporation errors in individual molecules within a cluster can occur (termed jackpot mutations). These factors make assembly and any related analyses challenging, with theoretical modeling suggesting that decreasing read lengths from 1000 to 100 bp can lead to a minimum of six-fold more decrease in contiguity. This can lead to misalignments and misassemblies in areas of low or high complexity, and impair phasing of variants. For these reasons, SRS of regions of repetitive DNA, high sequence homology, or extreme GC content remains challenging. Finally, with specific impact on virus genome sequencing, both Sanger sequencing and NGS shotgun sequencing are population-based detection (as opposed to single molecule/genome detection) so that their resolution is difficult at haplotype/swarm level, i.e., it is difficult to conclude that any two mutations are linked or associated with one another upon the same genome. Several modifications are now commercially available combining the use of SRS to produce longer synthetic reads, thereby attempting to take advantage of the high throughput and accuracy of short reads, and the benefits of longer reads. This is particularly important for viruses enabling the association of two mutations on the same template/genome. Approaches such as 10x Genomics Chromium use microfluidics to assign barcodes to shorter reads derived from a single template, although the sequencing reaction itself is still amplification driven. Additionally, utilizing long read sequencing (LRS) and SRS in parallel can provide greater accuracy and benefit of both approaches.

“Single molecule” sequencing represents the next evolution for high-throughput sequencing, sometimes termed “third generation sequencing”. Third generation sequencing platforms differ from SRS platforms by directly producing long reads with no amplification during sequencing. Currently two third generation technology platforms technologies are commercially available – Pacific Biosciences (PB) and Oxford Nanopore Technologies (ONT). Both platforms have been developed around novel biochemistries that enable the capture of long read DNA sequencing or cDNA from full length transcripts. Both technologies have higher rates of error (3%–15%) and different error profiles (mostly insertions or deletions) compared to short-read platforms; however, since such errors are random due to the nature of single-molecule sequencing, extremely accurate consensus can be achieved by aligning multiple concatenated copies of the same library, enabling the derivation of a consensus from a single sequence read containing repeated copies of the original DNA molecule. This is defined as “closed circular consensus” (CCS) or “read of insert” (ROI).

Pacific Biosciences

The early PB platform, the RS-II (released in 2010) had relatively short read lengths (~1–2 kb) (for a third-generation sequencer) and an average error rate of (~13%). Since then the technology has improved culminating in the release of a new machine in 2015 – the Sequel, which was also accompanied by a major improvement in single molecule real-time (SMRT) chemistry, providing an almost tenfold difference in output between the two machines. Furthermore, short templates ~1–2 kb can be circularized and sequenced repeatedly, in order to draw a CCS from the multiple copies of the same library. Briefly, hairpin adapters were ligated to either end of the template DNA molecule for generation of capped templates (SMRT-bell). DNA polymerases [otherwise known as Zero-mode waveguides (ZMW)] were located at the base of each nanowell, with a single molecule of DNA. All of this is located on a glass base, so that when fluorescently labeled nucleotides were flushed across the nanowells, during polymerization, fluorescent tags are cleaved off and released, with events being recorded in real-time. If the input DNA is relatively short (less than a few kilobase pairs), the molecule can be sequenced many times, creating a highly accurate consensus.

PB strength is in provision of linkage between individual SNPs, notably in the clinical setting. Studies have included tracing HCV drug resistance mutations, to tracking changes in the envelope genomic region to provide phylogenetic tracing between sexually linked clusters of cases. Additional studies have also applied this targeted protocol to HIV-1 and prevalence of drug resistance mutations. Transcriptomics studies have identified different patterns of splicing events between different families of viruses, with such events being rare in alpha-herpesviruses (Pseudorabies), baculoviruses, and orthomyxoviruses, but more common in beta- and gamma-herpesviruses, retroviruses and hepadnaviruses. The strength of PB in generating large datasets to understand viral transcriptomics was also demonstrated in a study using used 17 RSII SMRT cells and 1 Sequel SMRT cell, complemented with ONT MinION flow cells to produce a novel comprehensive long-read data reference dataset with which to explore transcriptomic variation in HSV-1 infection.

Oxford Nanopore Technologies

In 2014, Oxford Nanopore released a nanopore based sequencer called the MinION. This technology operated by monitoring the electrical conductance changes as nucleic acid (DNA/RNA) was passed through a molecular pore by a motor protein, whose main role was to slow the speed of translocation across the pore sufficiently that the changes were measurable. The smaller ONT platforms, such as the USB stick-sized MinION that costs only around US\$1000, were unique in this age of large, expensive machines since they offered relatively cheap start up investments and unparalleled portability, making in-the-field sequencing a possibility. As a result, the main appeal of ONT technologies has been its potential for mobile or frontline applications, which has been reflected in the number of studies focussing upon this approach with viruses including FMDV, Zika virus and Ebola virus and several plant pathogens. Since the MinION's release two larger models have been commercially marketed with the aim of increasing output by combining multiple nanopore flow cells: the GridION (up to 5 flow cells) and the PromethION (up to 48 flow cells).

This sequencing process generates 1D and 2D reads in which both “1D” strands can be aligned to create a consensus sequence “2D” read. The 1D raw reads have error rates of more than 10%, similar to PB raw reads. Although the error rates of 2D reads are somewhat improved, these were still higher than the consensus reads generated by SMRT sequencing. However, 2D reads were replaced, in 2017, by 1D² where sequencing adapters were added at either end of a piece of nucleic acid, meaning both strands i.e., complement, and template can translocate through the pore providing additional accuracy.

Since its release, there has been significant interest in using nanopore technology to sequence viruses, again, like PB, due to the ability to infer SNPs onto the same read and its portability, however, despite this interest, successful publications have been slow to appear due to the challenges of meeting the significant initial template requirements, which can be a particular issue when working with RNA viruses. There have however been notable successes with DNA viruses, including poxviruses and herpesviruses, due to greater ease in meeting such input requirements. Papers have used nanopore platforms to investigate metagenomics of the aquatic virosphere and transmission in outbreaks, including Ebola virus and Zika virus. Direct RNA sequencing (DRS), however, still has proven challenging, although the first publications are now appearing with Influenza, Coronavirus and PRRSV, demonstrating the potential of the method.

Merging SRS and LRS

Whilst LRS technologies mature and associated applications become established, SRS remains more cost effective, accurate and higher throughput. This is driving several groups to combine both platforms, thus gaining the benefits from both. Whilst the short-read platforms have high base accuracy and coverage, facilitating the identification of transcriptional start sites (TSSs), transcriptional end sites (TSEs), splice junctions and RNA editing, long-read sequencing is better suited to determining 5' and 3' UTR variants, splice isoforms, long non-coding transcripts and the detection of overlapping and embedded transcripts. Studies focussed upon merging both platforms have looked to identify linkage between SNPs in yellow fever virus (genus *Flavivirus*, family *Flaviviridae*), circoviruses (genus *Circovirus*, family *Circoviridae*) and African swine fever virus (ASFV; genus *Asfivirus*, family *Asfarviridae*). Of the above, the ASFV genome poses a unique challenge for NGS, particularly given its current importance as outbreaks spread across the globe, threatening the global porcine population. Its genome is composed of extensive homopolymer and repeat regions including inverted repeats (ITRs) of variable length, in addition to platform-specific limitations to homopolymer frequency should be considered. One study used ASFV-specific target enrichment, Illumina sequencing and long read Nanopore sequencing to generate high quality ASFV genome sequences which was used to correct a previously annotated genome prior to being used as a reference to investigate an outbreak in Moldova. Combined SRS and LRS approaches have also been applied to innate immunity activation in cells after infection with Influenza virus using Illumina-based transcriptomics and full-length PB sequencing of virus genes from single cells, characterising the transcriptomes of baculovirus (family *Baculoviridae*) and pseudorabies (genus *Varicellovirus*, family *Herpesviridae*) virus by combining the high accuracy Illumina reads onto third generation datasets.

Discussion/Conclusions

Next generation sequencing has now been available for 15 years, following the introduction of the 454 Genome Sequencer and pyrosequencing in 2005. Since then, numerous applications have been developed, which have revolutionised the way we view and understand viruses, both as pathogens and how they interact with their environments and hosts. Whilst short read technologies are still maturing, notably in the field of single cell sequencing, the emergence of third generation sequencing platforms are enabling researchers to identify hitherto unknown avenues of research, for instance the interactions of the virome and microbiome, and what implications this has for the health of the host. Additionally, HTS is responsible for the generation of a vast amounts of data which have ushered in new methods in computational biology. With single cell technologies and fourth generation advances, such as spatial transcriptomics now on the horizon it is an exciting time as genomics continues to push the cutting edge in virology. There is ongoing discussion of the increasing role of NGS in clinical diagnostics, with metagenomics type assays potentially not only taking the place of routine nucleic acid testing for blood donations and screening, but also carving out a niche in frontline diagnostic applications.

Glossary

Metagenomics The study of genetic material recovered directly from environmental samples. Traditionally, a natural sample is collected and subjected to nucleic acid extraction and sequencing. Thus, the term metagenome refers to the collection of genes sequenced from the environment.

Multiple-displacement amplification A non-PCR, isothermal based DNA amplification technique that uses

random hexamer primers and the high fidelity Φ 29 DNA polymerase. Sufficient DNA for genomics analysis can be obtained from minute amounts of starting DNA template.

Whole-genome amplification A molecular method to amplify the genetic material. In biology, there are different contrasting technologies that allow the amplification of minute amounts of nucleic acids. One such method is multiple-displacement amplification

Single-Virus Genomics: A New Tool for Viral Discovery

Viruses are by far the most abundant biological entities in the oceans, outnumbering any unicellular or multicellular organisms, and represent a major reservoir of genetic diversity that hides an enormous complexity across all marine habitats (Breitbart *et al.*, 2018; Paez-Espino *et al.*, 2016; Roux *et al.*, 2016; Suttle, 2007). Since the discovery by fluorescence microscopy of an unusual amount of ‘virus-like particles’ (VLP) in aquatic ecosystems in the advent of the 90’s, viral ecology has experienced a deep revolution and ‘shaken’ our understanding of marine science. Cultivation techniques for identifying, establishing, and maintaining virus-host systems in the laboratory, though very informative and necessary, are biased since the majority of microbial hosts remain uncultivable (Pedrós-Alió, 2012; Rappé and Giovannoni, 2003). Consequently, over the last decade much of the work carried out for characterizing marine viral diversity has employed a suite of culture-independent approaches, such as metagenomics (Brum *et al.*, 2015; Hurwitz and Sullivan, 2013; Roux *et al.*, 2016). Recently, thanks to researches at local and global scale, such as the Pacific Ocean Virome (POV), or the *Tara* expedition, global oceanic patterns of double-stranded DNA viruses (dsDNA) in surface oceans have been uncovered (Brum *et al.*, 2015; Hurwitz and Sullivan, 2013; Mizuno *et al.*, 2013; Roux *et al.*, 2016), albeit that the majority of the oceans, below mesopelagic, are mostly unexplored (Mizuno *et al.*, 2016; Roux *et al.*, 2016; De Corte *et al.*, 2019), and the documentation of their diversity has only just begun.

Metagenomics – the study of sequenced nucleic acids obtained from bulk environmental samples – provides a culture-independent way to discover novel microbial and viral genetic diversity. Commonly, metagenomic data deliver millions of short DNA reads (150–300 bp) from a viral community and later that complex ‘puzzle’ has to be assembled to deliver complete or draft viral genomes. In contrast, single-virus genomics simplifies this puzzle, as viral genomes are assembled from one virus at a time. In single-virus genomics (SVG), similar to single-cell genomics (Stepanauskas *et al.*, 2017), virus particles are fluorescently stained, sorted by flow cytometry and deposited individually in multi-well plates (Allen *et al.*, 2011; Martínez-Hernández *et al.*, 2017). Later, the capsid of the sorted single-viruses is ‘lysed’ and the genetic material is whole-genome amplified (WGA) and downstream sequenced. The most commonly employed WGA method is the multiple-displacement amplification (MDA). The chance of sorting and recovering a viral particle using this technique is directly dependent on its abundance. Therefore, genomes of abundant virus taxa in a given sample have a greater probability of being recovered. As discussed above, marine virologists have focused on unveiling global patterns of dsDNA viral populations at the family/genus and species levels in the oceans (Brum and Sullivan, 2015; Roux *et al.*, 2016). Despite the power of viral metagenomics, in 2017, the application of single-virus genomics to marine viral samples demonstrated that viral metagenomics had overlooked abundant and cosmopolitan marine viral populations in our planet (Martínez-Hernández *et al.*, 2017). Indeed, that study demonstrated that microdiversity hinders optimal metagenomic assembly, which could explain why the genomes of these abundant viral populations discovered by SVGs have not been identified before. That study, showed that the uncultured single-virus vSAG 37-F6 represented the, possibly, most abundant viral population in ocean surface waters and it was also present in the deep ocean. Now, we know that this uncultured virus is a pelagiphage (Martínez-Hernández *et al.*, 2019). The first single-virus genomic study was a few years before, in 2011 (Allen *et al.*, 2011), but it took a while to apply this technique to a natural environmental sample. In that pioneering study, the authors used fluorescence activated virus sorting to separate single viral particles of bacteriophages lambda and T4 and demonstrated that multiple-displacement amplification was suitable for achieving enough genetic material from a single virus for sequencing and assembling complete genomes. Since that report, so far, although incipient, this technique has been applied to several natural environmental samples, mainly marine, although recently, it was successfully used to sequence uncultured salivary viruses from humans (de la Cruz Peña *et al.*, 2018; Martínez-Hernández *et al.*, 2017; Stepanauskas *et al.*, 2017; Wilson *et al.*, 2017; Bhattacharjee *et al.*, Unpublished). We envision SVGs has great potential to accelerate discovery in the field of viral ecology. The following two sections

discuss and address best practices for applying single-virus genomics and provide all methodological details for laboratory implementation.

Best Practices and Protocol for Single-Virus Genomics

Sample Size and Preservation

Sample volumes used in single-virus genomics are typically in the order of milliliters. There are no agreed-upon standards as to what constitutes a useful sample size to study natural viral assemblages. Instead, sampling decisions should be guided by specific research questions and knowledge of the environment (e.g., estimated relative viral abundance). One milliliter of seawater can provide an insight into viral diversity that is comparable, or in instances superior, to the information derived from viromes produced from tens to hundreds of liters (de la Cruz Peña *et al.*, 2018; Martínez-Hernández *et al.*, 2017; Martínez Martínez *et al.*, 2014; Wilson *et al.*, 2017; Bhattacharjee *et al.*, Unpublished).

After collection, we recommend to store the samples at 4°C and proceed with fluorescence-activated virus sorting (FAVS) as soon as possible. If the sample cannot be processed within a few hours from collection, we strongly suggest preserving samples as described below in detail by following either cryopreservation or a mild fixation with glutaraldehyde. Samples for flow cytometry viral enumeration are usually fixed with 0.5% glutaraldehyde (final concentration) and stored at –80°C (Brussaard, 2004). However, that concentration of glutaraldehyde in the sample hinders WGA. Reducing the fixative to a final 0.1% concentration does not prevent DNA amplification and allows optimum flow cytometry (FCM) resolution of virus-like-particle groups (Martínez-Hernández *et al.*, 2017; Martínez Martínez *et al.*, 2014; Wilson *et al.*, 2017). Alternatively, we recommend, as in single-cell genomics for microbial cells (Martínez-García *et al.*, 2012; Stepanauskas, 2012), the addition of 10% glycerol Tris HCl-EDTA (glyTE, final concentration) prior to cryo-conservation at –80°C. Recent unpublished data from our laboratories indicate this method might be more suitable for SVG than glutaraldehyde fixation by providing a higher percentage of genome recovery (García-Heredia *et al.*, 2020).

Staining and Single-Virus Separation (Sorting)

Several methods are available to individually sort single cells, e.g., micropipetting (Zong *et al.*, 2012), microwell dilution (Gole *et al.*, 2013), or microfluidics (Prakadan *et al.*, 2017). Nevertheless, flow cytometry fluorescence-activated cell sorting (FACS) is the most commonly used method (Rinke *et al.*, 2014). Likewise, flow cytometry sorting is the preferred method for sorting individual viruses (FAVS) for SVG (Allen *et al.*, 2011; de la Cruz Peña *et al.*, 2018; Martínez-Hernández *et al.*, 2017; Martínez Martínez *et al.*, 2014; Stepanauskas *et al.*, 2017; Wilson *et al.*, 2017). However, microfluidics has also been successfully employed for sorting single viruses (Han *et al.*, 2015) and it is regarded as a promising technique for wider implementation (Schmidt and Hawkins, 2016).

Employing fluorescent dyes other than the commonly used DNA-specific SYBR® Green I (Brussaard, 2004) can aid in the detection and discrimination of, at least, certain free virus types. For example, we have noticed that SYBR® Gold dye performs better than SYBR® Green I for fresh unfixed marine samples. Also, for unfixed samples, washing steps with Tris-EDTA (TE) buffer before and after staining may improve detection and sorting of VLPs (Martínez-Hernández *et al.*, 2017), possibly by removing free environmental DNA (eDNA) which can create FCM background when stained with the fluorescence dye. Additionally, a DNase digestion step in solution is recommended to degrade the eDNA and DNA bound to cell debris, prior to adding the fluorescent stain. A control sample in which viruses have been removed (e.g., filtering through 0.02 µm) prior to adding the dye, may aid in discriminating VLP populations from instrument noise and eDNA background during FCM.

When possible, the flow cytometer has to be set in the most accurate mode for sorting single particles e.g., the single sort mode for the BD Influx sorter (Becton Dickinson, San Jose, CA). In addition, sorting at a very low flow rate helps avoiding sorting of doublets (two viruses in the same droplet; see recommended values for sorting viral marine sample in (Martínez-Hernández *et al.*, 2017; Wilson *et al.*, 2017)). Nanobeads with a 220 nm diameter (e.g., Sphero nano fluorescent particles, yellow 0.22 µm, Spherotech Inc.) should be used for instrument fine-tuning (e.g., voltage for fluorescence detection, flow rate; see details for fine-tuning in (Martínez-Hernández *et al.*, 2017)) to improve resolution of nano-particle detection.

As a final consideration, we should highlight the necessity of removing any traces of contaminating DNA within all reagents and material used during FAVS (Martínez-Hernández *et al.*, 2017; Rinke *et al.*, 2014; Woyke *et al.*, 2011). Even very small amounts of DNA contaminants may be amplified in downstream WGA masking, or prevent amplification of the targeted viral DNA which is in the order of femtograms.

Viral Capsid Lysis and Whole Genome Amplification

As a first step, viral capsids have to be broken down – lysed – to release the DNA so it is accessible for enzymatic amplification. Importantly, genome damage/degradation must be avoided during the lysis process. Virus particle lysis is typically achieved via temperature and/or pH shocks (Allen *et al.*, 2011; de la Cruz Peña *et al.*, 2018; Martínez-Hernández *et al.*, 2017; Martínez Martínez *et al.*, 2014; Stepanauskas *et al.*, 2017; Wilson *et al.*, 2017). Based on mixed results across previous published studies and recent

unpublished results from our laboratories (Garcia-Heredia *et al.*, 2020), the exact lysis treatment may necessitate tweaking for different virus types, possibly depending on specific protein capsid structures and the presence/absence of an envelope.

Multiple displacement amplification using Phi29 DNA polymerase has been the most common method for WGA. It has been used in the first application of SVG with cultures of lambda and T4 bacteriophages (Allen *et al.*, 2011), in marine environmental based studies (Martinez-Hernandez *et al.*, 2017; Stepanauskas *et al.*, 2017; Wilson *et al.*, 2017), and also in the first application of SVG to human-derived samples (de la Cruz Peña *et al.*, 2018).

Recently, EquiPhi29 (Thermo Fisher Scientific) – a thermostable mutant of the phi29 polymerase – has been proven to significantly improve genome recovery and to reduce amplification reaction time (Stepanauskas *et al.*, 2017). Another improvement toward enabling near-complete WGA from single cells may be TruePrime® RCA (Sygnis/Expedeon), which combines the Phi29 polymerase with the *Thermus thermophilus* (Tth) PrimPol's primase activity preferring dNTPs as substrates for synthesizing DNA primers (Picher *et al.*, 2016).

Sequencing

In the single-virus genomic studies mentioned above, single-amplified virus genomes were sequenced using mainly Illumina technology (pair-end 150–300 bp $\times$ 2). We recommend at least a sequencing coverage of $\times$ 1000 per single virus (assuming a mean viral genome size of 40 kb). Very recently, some single-viruses from our lab have been successfully sequenced by Nanopores proving that this technology is compatible with MDA products. Thus, the novel long-read sequencing platforms, such as Pacbio or Nanopore will undoubtedly have potential for improving genome assembly and completeness of single viruses in further studies.

Detailed Protocol

The following protocol is best suitable for aquatic samples but may be applicable to samples of another nature, e.g., soil, tissue, blood or other bodily fluids, following extraction of the viral particles from other materials in the sample, purification, and resuspension in a suitable solution, such as water or Tris HCl-EDTA buffer. A similar workflow can be applied to solid samples, such as soils, as long as viruses have been previously resuspended.

Sample Collection and Preservation

Step 1: Collect 5–50 mL of your sample in sterile tubes.

- If viral abundance is low, sampling volume might need to be adjusted.

Step 2: Optionally, samples can be filtered through a 0.2 μ m filter to remove cellular fractions or a natural sample can be processed unfiltered. The latter procedure is recommended since it ensures that large viruses remain in samples and are not removed in the filtration step. However, in the former, the viral fraction has increased purity and is free of potential co-contamination and co-sorting of single-cells during sorting. In any case, after sampling, always keep samples at 4°C until sorting.

- Bear in mind that this filtration step could remove some viruses, especially large viruses. Depending upon the objectives of the study and the target viruses, other methods such as centrifugation, can be used to separate viruses from cells, or even filtration can be omitted. In this case, FAVS must be done as soon as possible to avoid changes in the community structure. However, as discussed below, preservation of samples can be applied.

Step 3: If sorting cannot be performed on the same sampling day, the sample could be preserved in 10% GlyTE buffer as detailed below:

- (1) Prepare GlyTE mixing 20 mL 100 $\times$ TE pH 8.0, 60 mL deionized water and 100 mL molecular-grade glycerol.
- (2) Filter GlyTE through a 0.2 μ m filter.
- (3) Add 100 μ L of GlyTE buffer to 1 mL of sample.
- (4) Mix for 1 min.
- (5) Store at -80°C until use.

Alternatively, samples can also be preserved in formaldehyde at 0.1% v/v final concentration and the sample stored at -80°C until required.

Viral Staining

If the sample has been cryopreserved, thaw it on ice and begin the staining procedure as follows:

- (1) Add sample (1 mL approx.) to a 10 kDa centrifugal filter (e.g., Nanosep 10 kDa (OMEGA, Pall Life Sciences)).
- (2) Centrifuge at maximum speed for 2 min, to concentrate the viral sample.
- (3) Add 500 μ L of sterile TE buffer to the sample in the centrifugal filter device.
- (4) Mix and resuspend by inversion and vortex strongly for 15 s

- (5) Transfer viruses in TE to a new Eppendorf tube.
 - (6) Add 2.5 μL of SYBR-Gold working solution (1/10 dilution of stock) 0.02 μm filtered to the 500 μL of viral sample.
 - (7) Stain at room temperature, in the dark for 20 min.
 - (8) Transfer staining viral sample to a 10 kDa centrifugal tube.
 - (9) Centrifuge at maximum speed for 2 min up to 50 μL approximately.
 - (10) Discard the eluate and add 500 μL of sterile 0.02 μm -filtered TE buffer to the viruses.
 - (11) Mix by inversion and centrifuge at maximum speed for 2 min, to wash the remaining free SYBR Gold dye from the sample.
 - (12) Repeat washing step 2 more times.
 - (13) Add 500 μL of sterile 0.02 μm -filtered TE buffer to the sample.
 - (14) Mix carefully and recover the stained viral fraction into a new Eppendorf tube.
 - (15) The sample is ready for sorting.
- Autoclaved TE buffer used in the staining procedure is previously ultraviolet treated for 16 h and 0.02 μm -filtered through Anotop filters (Whatman).
 - We advise filtering all solutions through 0.02 μm syringe filters before using.
 - An identical staining procedure can be done with a 0.02 μm -filtered, UV-treated TE buffer, to use as a blank before the viral sample sorting.

Fluorescence-Activated Virus Sorting

DNA decontamination and fluorescence-activated virus sorting preparation

- (1) For a DNA decontamination procedure for a flow cell sorter, we recommend strictly following the recommendations of [Rinke et al. \(2014\)](#). In brief, if the sample is from a marine environment, prepare at least 4 L of sterile 1 $\times$ phosphate buffered saline (PBS) one day before sorting to use as sheath fluid. Decontaminate the sheath fluid and the sheath tank of the sorter by overnight UV exposition by opening the tank and placing it into a laminar hood with a UV-lamp (for more details see [Rinke et al., 2014](#)). On the day of sorting, run 1 L of sodium hypochlorite (bleach) 0.3%–0.8% final concentration, in deionized water, through the fluidic line of the sorter for 2 h. Clear the hypochlorite solution by running 1 L of sterile water through the fluidic tubing for at least 30 min as per the recommendation ([Rinke et al., 2014](#)). If the sorter is within a laminar flow hood with a UV lamp, bleach all the internal accessible surface of the sorter and hood, and UV treat for 30 min prior to analyses and sorting.

Preparation of 384-well plates for sorting

- (1) Use autoclaved 384-well plates for sorting (note: some commercially available multiwell plates are not sterile).
 - (2) Add 0.6 μL of the UV-treated sterile TE buffer to each well.
 - (3) UV-treat the 384-well plates containing TE buffer for 10 min.
 - (4) Seal the plates and keep at low temperature (4°C) until sorting.
- Plates not used for sorting can be stored at -20°C for further use. In some cases, after freezing, plates can become slightly distorted, which can affect the deposition of the droplet containing the single-virus in the center of the well.
 - Immediately before sorting, the plates should be centrifuged at low speed to make sure the TE buffer is in the bottom of the well.

Sorting

- (1) Stained viral samples should be screened through a 35–40 μm mesh-size cell strainer (e.g., BD Biosciences) to ensure the removal of large particles that can potentially clog the fluidic line during sorting.
- (2) Analyze your stained viral sample in green fluorescence detecting side scatter (SSC) and/or forward scatter (FSC). Stained blanks will aid in defining the target sorting population gate. At this point, the experience of the flow cytometer sorter operator is paramount. Please refer to a previous reference protocol developed by ([Brussaard, 2004](#)) to detect viruses by flow cytometry. Nanoscale fluorescent beads (e.g., 220 nm 1-peak yellow beads (Sphero Nano Fluorescent Particles (SpheroTech Inc.)) may be run to set up and fine tune the sorter (for details see [Martinez-Hernandez et al., 2017](#)).
- (3) Sort an individual viral particle per well in the plate. Leave 2–3 columns or rows without sorted viruses to use as a negative control during MDA. Use several wells (e.g., 4–10) for sorting multiple virus particles (e.g., 10 per well, 20 per well and 100 per well). ([Fig. 1](#))
- (4) Seal the plate immediately after sorting and store it at -80°C .

Whole-Genome Amplification

Preliminary notes:

- The whole genome process and reagent preparation are done in a dedicated laminar flow hood.
- A lab coat, gloves, sleeves cover, protection glasses, and a mask should be worn. Bleach your gloves frequently.

Fig. 1 *Single-virus genomics workflow.* Viruses are fluorescently stained (e.g., SYBR Gold for dsDNA viruses) and sorted one at a time from the natural sample using fluorescence-activated virus sorting (FAVS). Sorted single viral particles are deposited in multi-well plates and then the capsid is lysed by a combination of pH and temperature shock. Free viral DNA is then subjected to whole genome amplification (e.g., real time multiple-displacement amplification, MDA). After amplification, enough DNA is available for DNA sequencing or target screening.

- Always handle all reagents using coolers to maintain low temperatures. Bleach the surface of tubes and reagents with a wipe.
- Water used in whole genome amplification has to be sterile deionized water and UV-treated for 16 h.

For more details, see [Rinke *et al.* \(2014\)](#).

DNA decontamination

- (1) Carefully clean all laminar flow hood surfaces, and all eppendorfs and tubes employed for the WGA amplification, with new prepared 10% bleach in deionized water.
- (2) Before WGA, UV-treat the laminar flow hood for 1 h.

Reagent preparation

- (1) DLB buffer (Quiagen 1031206) is used for viral lysis.
- (2) Stop solution (Quiagen 1032393) is used to neutralize the effects of the direct lysis buffer (DLB). It comes ready for use.

DLB preparation

- (1) Add 500 μ L deionized UV-treated water to the lyophilized DLB.
 - (2) Thaw 1 M DTT, vortex and add 45.5 μ L.
- You need 800 μ L of DLB buffer per 384-well plate.
 - Any leftover can be stored at -20°C and used in the next whole genome amplification (Only one thaw cycle is allowed).
- (1) Vortex both tubes and seal using parafilm.

Stop solution

- (1) Add 900 μ L of stop solution to a new Eppendorf tube.
- Any leftover can be stored at -20°C and used in the next whole genome amplification (Only one thaw cycle is allowed).
- (1) Seal the Eppendorf tube with the 900 μ L of Stop solution using parafilm.

DNA decontamination of DLB and stop solution

- UV crosslinker CL-1000 UVP was used to irradiate the reagents ($999.9 \mu\text{J cm}^{-2}$). Other UV crosslinkers can be used, but we strongly suggest to estimate the UV dose according to the UV lamp used.
- (1) Put the Eppendorf tubes containing DLB and Stop solution floating on sterile deionized water in a cooler unit at 8 cm distance to the UV bulbs.
 - (2) UV-treat the tubes for 30 min on one side.
 - (3) Vortex the tubes.
 - (4) UV-irradiate for 30 more minutes on the other side.

Master mix preparation

The whole genome amplification described here is done applying the modified WGA-X method (Stepanauskas *et al.*, 2017) which uses the novel thermotolerant EQUIPhi29 DNA Polymerase (Thermo Fisher Scientific).

8.0 μL of master mix should be added to each well, containing:

- 5.50 μL of sterile deionized and UV-treated (16 h) water
- 1.00 μL of Reaction buffer (supplied with the EQUIPhi29 DNA pol)
- 0.4 μL of dNTPs 10 mM each
- 0.1 μL of DTT 1 M
- 0.8 μL of heptamers 0.5 mM
- 0.2 μL of EQUIPhi29 DNA polymerase ($10 \text{ U } \mu\text{L}^{-1}$)

Calculate the total volume needed for your sample, considering the pipetting error.

e.g., For a 384-well plate and considering a 20% pipetting error, total volumes would be:

- 2534.86 μL of sterile deionized and UV-treated (16 h) water
- 460.80 μL of Reaction buffer (supplied with the EQUIPhi29 DNA pol)
- 184.32 μL of dNTPs 10 mM each
- 46.08 μL of DTT 1 M
- 368.64 μL of heptamers 0.5 mM
- 92.16 μL of EQUIPhi29 DNA polymerase ($10 \text{ U } \mu\text{L}^{-1}$)

Divide to the total volume in Eppendorf tubes (maximum 750 μL per tube), seal them with parafilm and irradiate them as for DLB and Stop solution, but for a total time of 30 min (vortex and turn them after the first 15 min).

After the UV irradiation step, add SYTO-9, 1.25 μM final concentration, and store at 4°C until use. SYTO-9 dye is UV photosensitive.

The whole genome reaction procedure

- (1) Thaw and spin down the plate with the sorted single-viruses.
- (2) Place the plate in a cooler.
- (3) Add 0.7 μL of DLB to each well and mix thoroughly to “lyse” the viruses.
- (4) Incubate for 10 min at room temperature. Seal the plate and spin it down.
- (5) Add 0.7 μL of stop solution, and mix thoroughly again, to neutralize the DLB.
- (6) Seal and spin down the plate.
- (7) Add 8 μL of the master mix (with SYTO-9 added) to all samples and mix thoroughly.
 - (a) Carefully add 1 ng and 10 ng of viral DNA positive control to some empty wells with no viral sorted particles. Dedicate at least 4 wells for the positive control. *Positive controls should be placed in peripheral wells to minimize the risk of contamination.*
- (8) Seal and spin down the plate.
- (9) Run the multiple displacement amplification (MDA reaction) at 45°C for approximately 4 h in a plate reader. Time can be adjusted according to the efficiency of the reaction by monitoring the positive and negative control wells. Positive control wells should amplify in 30 min, while negative start to amplify after 4 h approx. Single-viruses should amplify in between those 0.5–3 h approximately.
- (10) After 4 h stop the MDA reaction incubating samples at 75°C for 15 min.
- (11) Make a 1:10 dilution in a new plate adding 1 μL of MDA product and 10 μL of sterile TE 0.02 μm filtered and UV-treated buffer.
- (12) Store the MDA product and dilution plate at -80°C .

Biophysical Characterizations in the Solution State

Robert P Rambo and Katsuaki Inoue, Diamond Light Source, Didcot, United Kingdom

Introduction

Structural investigations in the solution state provide the opportunity to study biological particles in near native conditions. Solution-state small angle X-ray scattering (SAXS) has a long history as a complementary technique to high resolution structural methods such as X-ray crystallography (MX), nuclear magnetic resonance spectroscopy (NMR) and now, cryo-electron microscopy (EM). SAXS can efficiently validate structural hypotheses, answering the basic question “Does the high-resolution atomistic model exist in solution?” Additionally, SAXS is often used to model missing tails or loops from high resolution structures as everything in the path of the incident X-ray beam will scatter X-rays. Consequently, atomistic interpretation of a macromolecular SAXS experiment relies critically on constraints provided by prior chemical knowledge (e.g., secondary structure assignments, dihedral angle restraints) and molecular dynamics. The coupling of SAXS with computational approaches allows SAXS experiments to be interpreted at the residue-level and has led to insightful structure-function relationships.

A solution state SAXS measurement is a resolution-limited, picture of the conformational landscape determined at a given condition (i.e., salt, pH, temperature). For flexible systems, the modeling of SAXS data requires extensive computational searches. Here, flexibility is inferred by the requirement of multiple conformations to satisfy the SAXS observations. Residues enabling chain dynamics must be assigned during the computational searches which are often identified by limited-proteolysis, NMR, sequence alignments and secondary structure predictions. The validation of flexibility by SAXS is challenging as the time-resolution of SAXS has often been too slow to capture the micro- to milli-second (ms) time scales of many biological functions. Alternative methods must be pursued such as synchrotron-based X-ray Footprinting and Mass Spectrometry (XFMS) and Diffracted X-ray Tracking (DXT).

XFMS and DXT are solution-state methods capable of informing on sub-millisecond reaction time-scales. XFMS is a destructive method that interrogates the solvent accessibility of residues using X-ray induced radiolysis of water. Residues that are highly accessible to a water molecule will form hydroxyl adducts that are subsequently identified using mass spectrometry. Many internal waters will change their occupancies during a conformational change and XFMS has allowed identification of functionally critical waters protein structures. XFMS reactions occur within the sub micro-second to micro-second time window enabling interrogation of biological relevant time-scales. Likewise, DXT is a true, real-time, time-resolved technique that informs directly on dynamics. DXT requires the attachment of a gold nanocrystal to label the biological particle. Polychromatic X-rays will diffract from the gold nanocrystal producing a single diffracted spot that moves as the protein wiggles about in solution. High-speed X-ray cameras are used to track changes in the diffracted spot at nano-second time resolutions. Both XFMS and DXT can also be performed using *in vivo* systems, allowing for direct observations of the biological particles in native conditions.

Solution-State Small Angle X-Ray Scattering

Small angle X-ray scattering in the solution state examines the scattering of X-rays by particles in solution. The particles are assumed to be randomly oriented and at sufficiently dilute conditions such that there does not exist any interparticle interactions or correlations. These conditions comprise the prototypical bioSAXS experiment and the SAXS signal is recovered as a background subtracted measurement. Contemporary bioSAXS is routinely performed using size-exclusion chromatography coupled instruments where SAXS measurements are made during purification of the sample that ensures both sample homogeneity and ideal background subtraction.

The scattering of X-rays is by electrons and it is the spatial arrangement of the particle's electrons that provide the observed SAXS signal. Here, the particle's distribution of electrons is known as the particle form-factor, $A(q)$, which is a function of scattering-vector, q . Changes in the particle's conformation will cause a comparable change in the particle's form-factor and consequently in the shape of the SAXS curve. Since SAXS curves can be readily calculated from atomistic or high-resolution models, SAXS offers an efficient method for validating the solution state.

Solution-state SAXS is an ideal investigative tool for studying viruses as assembled viruses are hierarchical structures with dimensions much larger than their constituent capsid proteins. Time-resolved SAXS experiments allow for the simultaneous detection and monitoring of the smaller structures that are required to nucleate and form the much larger capsid structure. Furthermore, SAXS is often used to detect and model conformational changes. SAXS studies on the C-terminal transmembrane domain (TMD) from parainfluenza virus (PIV) demonstrated lipid dependent conformational changes. The effect of this conformational change was further explored using model membranes that showed that the TMD induces a negative topological curvature in membranes suggesting an active role in membrane fusion.

SAXS studies of the matrix (m) protein from the Newcastle disease virus (NDV) revealed the protein exists as a stable dimer in solution that self assembles at neutral pH into a hollow helical structure by recruiting tetramers of m-NDV protein. A shift to acidic environment disassembles the hierarchical structure and stabilizes dimer formation. These observations were readily made by performing SAXS experiments at different pH conditions. Furthermore, since SAXS measures the molecular form-factor, shape retrieval algorithms could be applied which consequently revealed the shape of the m-NDV dimer and its hierarchical helical structure.

Fig. 1 Popular applications of bioSAXS experiments. (A) All atom solution-state SAXS model of HCV IRES (red) containing domains II, III and IV. Model is overlaid with low resolution cryo-EM density (yellow) extracted from the IRES bound to large ribosomal subunit. (B) Detection of conformational change within amphipol-stabilized G-protein coupled receptor in presence (purple) and absence (ligand) of ligand. P(r)-distribution is the set of all paired-distances with the particle as measured by SAXS. A comparable change in the P(r)-distribution suggests conformational change (image adapted from). (C) SAXS based reconstruction (purple) of a protein RNA complex (green, orange, cyan) using IKETAMA (Diamond Light Source, UK). (D) Volumetric *ab initio* model of Tetrahymena telomerase p65 RNA (mesh). Atomistic model suggest two of the four helices are co-axial stacked in solution. Structural basis of smoothened regulation by its extracellular domains. *Nature* 535, 517–522.

Throughout their life-cycle, viruses form a variety of complexes with host nucleic acids, proteins and small molecules, and SAXS has been a core technique for validating oligomeric states and shapes, providing low-resolution models and suggesting new functions (Fig. 1). Combined SAXS and molecular modeling on RNA fragments from HIV-1 genome specifically containing the transactivation (TAR)/polyadenylation (polyA), primer-binding site (PBS), and Psi-packaging domains were able to propose atomistic models that allowed direct interpretation of the SAXS data at the residue level. Notable changes in the tRNA-like element loop suggested a function required for release of the tRNA primer in genome replication. Similarly, a SAXS-based approach determined a full-length model of the Hepatitis C Virus (HCV) internal ribosome entry site (IRES) that revealed the structure of the IRES free in solution. SAXS based modeling is an effective strategy for determining highly structured RNA or DNA elements derived from viral genomes. Furthermore, combined NMR and SAXS studies on viral chaperone phosphoprotein P from Nipah virus showed P is globally disordered and persists as a disordered protein when bound to its target viral nucleoprotein, N⁰. The disorder is hypothesized to be required for P to act as a tether for enriching N⁰ at the site of viral RNA synthesis.

SAXS as a Structural Tool (Theoretical Considerations)

There are various mathematical formalisms to describe SAXS including atomistic modeling, form-factor fitting and indirect Fourier transform (IFT). An IFT relates the set of all electron-electron paired distances, P(r)-distribution, within the macromolecule to the SAXS intensities (Fig. 2). The P(r)-distribution is a histogram of all intermolecular distances and is equivalent to the squared particle form-factor. The P(r)-distribution informs on the maximum dimension of the particle, the radius-of-gyration (distribution of mass about the particle center) and likewise, will demonstrate conformation dependent changes. The P(r)-distribution is

Fig. 2 SAXS basics. A measured SAXS curve (orange curve, left) is made in reciprocal space where the scattering vector, q , is in reciprocal nm or Å. SAXS is a resolution limited measurement meaning scattering at higher q values delivers higher resolution. At low resolution, SAXS of a particle can be approximated by its overall shape. The Fourier sine-integral transform of the SAXS curve produces the paired-distance, $P(r)$ -, distribution function (blue curve, right) measured in real-space units. The $P(r)$ -distribution is a histogram of all interatomic paired-distances within the particle. The $P(r)$ -distribution determines the maximum dimension, d_{max} , of the particle. The shape of the SAXS curve is determined by the shape of the scattering particle. Here, a nearly spherical shape will demonstrate oscillating features in the SAXS curve.

resolution-limited, implying SAXS data collected to higher resolution will support additional features within the distribution. Since a bioSAXS measurement is made from the ensemble of billions of molecules, it is more accurate to describe SAXS as a structural measurement of the ensemble and the $P(r)$ -distribution is a sum of all members in the ensemble.

Alternatively, form-factor fitting attempts to describe SAXS data using simplistic models such as spheres, cylinders, or ellipsoids (Fig. 3). These models assume homogeneous electron densities (ρ) but can be extended to heterogeneous electron densities using a core-shell approach. All viruses can be coarsely described as either a two-phase (protein and nucleic acid) or three-phase (protein, nucleic acid and lipid) particle. The nucleic acid phase (ρ_{core}) has a greater electron density than the protein (ρ_{shell}) and likewise, the protein has a greater electron density than lipid. Form-factor fitting of filled virions determines shell thickness (capsid coat), diameter of the virus and possibly, the thickness of the lipid envelope. These are all fitted parameters and can be used to follow overall structural changes in a virus (such as swelling) at different pH levels and salt concentrations. Furthermore, assuming that the electron density contrasts (ρ) for protein and solvent are constant, form-factor fittings allows for the quantitative determination of nucleic acid content within formed virions.

The core-shell formalism (Fig. 3) shows that the magnitude of the SAXS scattering due to each respective phase is dependent on the magnitude of the ρ difference. Since $\rho_{solvent}$ can be effectively modulated through increases in either salt or monovalent salt concentration, there will be a match point concentration where the effective contrast difference between $\rho_{solvent}$ and ρ_{shell} is zero. At the match point, the measured SAXS signal will only be due to the contents of the inner core (Fig. 3). If sucrose is used as the contrasting agent, the match point will be greater than 50% sucrose. High sucrose concentrations support many proteins and complexes in solution, however, reducing the contrast of the protein will also reduce the contrast of nucleic acid. This places a high demand on sample concentration to mitigate errors in background matching. For nucleic acid filled capsids, concentrations greater than 10 mg per ml can be expected.

Fig. 3 Core-shell modeling. (A) Form factor fitting describes the scattering of the particle by amplitude function where the square of the amplitude is proportional to $I(q)$. A spherical core shell model is described by two spheres of different radii and electron density contrast (ρ_{shell} and ρ_{core}). The amplitude contributions of the core and shell are weighted by their respective volumes, V_c and V_s and effective contrast differences (ρ_{core} and ρ_{shell}) and (ρ_{shell} and ρ_{solvent}). (B) SAXS of a two phase particle with a d_{max} of 100 Å modeled with a shell thickness of 22 Å (orange). Contrast matching the shell (dark gray) causes a shift in the SAXS curve due to the apparent smaller diameter. (C) Real-space $P(r)$ -distribution demonstrates a reduction in d_{max} . An empty virus will have a core that has the same electron density as the solvent. This shifts the $P(r)$ -distribution to the right (green) as most of the particles' distances are contained within the shell.

Recent application of contrast variation to nucleic acid filled MS2 virions have allowed for the visualization of the RNA genome in intact virus showing an asymmetric, compact shape. Comparison of the RNA genome free of the capsid shows the viral RNA unpacks into a discrete extended structure that is not a random coil. It suggests the final packing of the RNA is facilitated by interactions with MS2 coat protein. Exploiting the contrast differences between protein and nucleic acids in complexes has been a popular application in SAXS where the difference allows for the separate modeling of each phase in *ab initio* reconstructions (Fig. 1(E) and (F)).

Time-Resolved SAXS

Studying virus particles by SAXS will typically require $\sim 10^{10}$ X-rays photons in a single exposure to provide meaningful low-resolution information ($q_{\text{max}} < 0.2 \text{ \AA}^{-1}$). For most synchrotron-based monochromatic X-ray sources, this implies the shortest possible time-scale that can be measured is around 1–10 ms using a stopped-flow kinetics sample environment. However, for studying kinetics of virus assembly, at least 10^{11} photons will be required to follow capsid nucleation events which may not be possible for short exposures of less than 10 ms. To access smaller time-scales ($< 1 \text{ ms}$) by SAXS using a monochromatic X-ray source, continuous mixing experiments can be performed where a reaction is initiated in a mixing chamber and flowed into the SAXS sample cell. Reaction time points are determined by the distance from the point of mixing and flow rates. Extended exposures can be performed if the flow rate is fixed, substantially increasing the signal-to-noise of the measurement (Fig. 4).

Time-resolved stopped flow experiments were performed examining the assembly of Hepatitis B capsids in the presence and absence of RNA. Exposures were limited to 5 ms however, the mixing time was much slower at 60 ms suggesting the earliest possible time point that can be measured is $\sim 65 \text{ ms}$ after mixing. This was sufficient to observe the condensation of the capsid proteins onto the RNA

Fig. 4 Time-resolved SAXS analysis. (A) Each measured time point, i , corresponds to a SAXS frame that contains both the particle amplitude, $A(q)$, and corresponding background term. Given each subsequent measurement ($i + 1$) corresponds to a small change in time assuming negligible background differences, the effective difference between each time point measures the change in the particle amplitude or $P(r)$ -distribution. (B) Intensity difference curve modeled from swelling of a two-phase core-shell model (in Fig. 3). Protein phase was allowed to swell by 5 Å. (C) Difference curve transformed to real-space showing swelling shifts peak distances to right.

followed by isomerization to the mature capsid (Fig. 5). The SAXS camera covered the length scales from 14 to 785 Å during each measurement. During the time-resolved assembly of the virion, the contributions of each component (free RNA and protein, partially assembled RNA-protein complexes, and substates of the virion) to the SAXS signal is additive. At the earliest time point, the mixture will mostly contain free RNA, protein and partially assembled complexes whereas at the later time points, the SAXS signal will be due to the assembled virion. The signal deconstruction technique, multivariate curve resolution (MCR), can then be applied to the entire set of time-resolved measurements to determine a set of basis SAXS curves that describe the component species in solution. MCR helps reveal the folding pathway of the protein-RNA complex during assembly of the virion.

Diffracted X-Ray Tracking

Diffracted X-ray tracking (DXT) monitors the tilting and twisting motions of individual polymers to be followed within the microsecond to millisecond time scales (Fig. 6). For biological applications, DXT uses a small gold nanocrystal as a labeling probe that is covalently attached to the protein or nucleic acid through an accessible thiol group. The thiol group is often engineered through standard site-specific mutation methods. Under dilute conditions, the biological particles are subsequently adhered to a surface substrate such as Kapton. Each electron dense gold nanocrystal will diffract X-rays and by using a wide energy band-width X-ray source (Laue diffraction), any motion of the nanocrystal will consequently cause a movement in the observed diffracted X-ray spot.

Fig. 5 Time-resolved SAXS of Hepatitis B virus capsid assembly. (A) SAXS curves from ~ 65 ms to 30 s following assembly of viral protein Cp185 with 40 nucleotide RNA. RNA contains preferred binding sites of Cp185. (B) Multivariate curve resolution of the time-resolved SAXS curves suggest 5 major species evolve through the assembly of the capsid. Initial stages suggest dimerization of proteins on the RNA followed by stable hexamer formation. The hexamers condense into a stable 80-mer complex followed by complex capsid formation. Images adapted from Oliver, R.C., Potrzebowski, W., Najibi, S.M., *et al.*, 2020. Assembly of capsids from hepatitis B virus core protein progresses through highly populated intermediates in the presence and absence of RNA. *ACS Nano* 14 (8), 10226–10238.

Each diffracted spot corresponds to a single protein molecule. Therefore, the movement of the spot is a single molecule event that traces a track in the set of recorded images using a high-speed X-ray camera (> 1 MHz). Each track is resolved into two time-resolved angular components χ (twisting) and θ (tilting) that describe the motion of the nanocrystal. DXT will record tens of thousands of tracks that form an empirical distribution of χ and θ . These distributions describe the non-random degrees-of-freedom accessible to the protein. The distributions can change in the presence of ligand, when bound to a cofactor or partner or due to a mutation.

DXT is a novel technique with considerable potential for virology, although to date it has been applied to only a handful of macromolecules. One example is the group II chaperonin, a large macromolecular machine that converts the energy in ATP to useful work. Time-resolved studies were initiated using caged-ATP that followed the mechanical cycle of the chaperonin. DXT demonstrated non-concerted motions between the subunits where ATP binding promotes twisting and closing of a subunit. The time-resolved, single-molecule studies proposed an asynchronized closing motion of the eight subunits challenging the synchronization model proposed by previous cryo-EM studies.

Furthermore, DXT has been applied to several membrane protein systems including bacterio rhodopsin (bR), KcsA potassium channel, nicotinic acetylcholine receptor (nAChR), major histocompatibility complex (MHC) and G-protein coupled receptors (GPCRs). Studies on nAChR in the presence and absence of ligand (ACh) revealed a fundamental dynamic in the gating mechanism of nAChR, which showed that the first motion related to the ligand (ACh) binding initiated vigorous molecular fluctuations in nAChR that subsequently triggered the gating mechanism. The nAChR channel was labeled through an engineered thiol group, however, in studies of the MHC complex, the recognition peptides were labeled with the gold nanocrystal. This allowed peptides to be flowed in such that dynamics of peptide binding could be followed in real-time.

DXT is a highly specialized technique that is gaining support. Sample quantities are 1 μ L at < 0.1 mg per ml and the method has not been applied to viral systems. However, DXT could be an invaluable scientific tool in virology. The single molecule tracking, small sample requirements and ease-of-use would afford microsecond time-scales to studying structural changes in

Fig. 6 *Diffracted X-ray Tracking (DXT).* (A) Gold nanocrystals coupled to proteins via thiol chemistry will wiggle in solution. The intrinsic motions of the protein are non-random and will move the gold nanocrystal in either a twisting (χ) or tilting (θ) motion. The [111] diffraction condition is detected using a broad band X-ray source and motions are recorded with a high-frame rate detector (> 100 kHz). Protein coupled motions of the crystal will be recorded as moving diffracted spots (tracks). (B) Each diffracted spot corresponds to a single-molecule and tens of thousands of tracks are recorded in a typical DXT experiment. component proteins of the capsid, packaging of the genome, receptor interactions required for infection and a new assay for intrinsically disordered proteins. For example the pH initiated conformational changes of virus fusion machines could, for the first time, be directly studied using photo-release of caged protons as a trigger. Current research has also applied DXT to living cells where target GPCRs are transiently expressed in HEK 293 cells. The cells are grown on the Kapton support and used directly in the DXT measurement. The ability to monitor structural changes at biological relevant time-scales *in vivo* can help resolve or validate difficult hypotheses. In SAXS, flexibility is an inferred property and DXT has been used to directly test the flexible hypothesis of a coil-coiled protein and demonstrate stiffening due to a mutation which causes severe errors in meiosis.

X-Ray Footprinting Mass Spectrometry

X-ray footprinting is a technique that activates water molecules through radiolysis producing a highly reactive hydroxyl radical chemical probe. A synchrotron X-ray source is used to provide a broad-energy bandwidth at extremely high flux ($> 10^{15}$ photons $\cdot$ second $^{-1}$) in < 100 μ m-square spot. This induces rapid generation of hydroxyl radicals in the sample. The duration of the X-ray bursts controls concentration of hydroxyl radicals in the sample which is adjusted to minimize side reactions such that only the residues in the protein are reacting with the chemical probe. The detector for XFMS is a mass spectrometer and modified amino acid residues are subsequently identified by peptide fragmentation and mass spectrometry.

For each sample, a series of short exposures (< 10 ms) is performed to determine the hydroxyl reaction rates for the amino acids in the structure. Variation in the reaction rate is related to how buried or solvent accessible a residue is in the folded structure. More importantly, reaction rates can be followed as a function of treatment (ligand, pH, temperature). Functionally important residues in a binding reaction may become more buried showing a decrease in reaction rate. Likewise, some residues may become more solvent exposed demonstrating an increase in reaction rate. XFMS has been applied to a wide variety of systems including protein nucleic acid complexes, membrane proteins (GPCRs and ion channels) and *in vivo* mapping of the ribosome.

XFMS is a high information technique that not only identifies which residues are solvent exposed but also which atoms in the residue are reacting. This can be appreciated in a cryo-EM investigation of the SARS-CoV-2 spike protein that investigated the binding modes of various high affinity nanobodies. Not all nanobody-spike complexes were suitable for cryo-EM structure determination and XFMS allowed direct mapping of the residues involved in the interaction. The spike protein residues mapped far from the host-cell angiotensin converting enzyme (ACE) 2 binding site suggesting neutralization by the nanobody occurred through an indirect, non-competitive mechanism.

Concluding Remarks

Biophysical characterizations in the solution-state are critical to validating structural hypotheses derived from high resolution structure determination methods. As described, SAXS is a powerful tool that informs on the solution state of macromolecules. SAXS provides a comprehensive and composite picture of all the conformations in the ensemble. This allows SAXS to be used to complete partial high-resolution models, refine homology models, determine the structure of complexes and reliably test the structural hypothesis from MX and cryo-EM. More importantly, SAXS can reveal novel conformations hidden from high-resolution methods, essential for studying assembly/disassembly pathways of a virus. The information in a SAXS measurement is sufficient for modeling conformational changes when coupled with advanced computational methods such as molecular dynamics. More direct validation of dynamics can be achieved using DXT. DXT reveals, in real-time, the intrinsic motions of single molecules at microsecond time-scales. These observations show how a protein “wiggles” in solution allowing functional identification of intrinsically disordered regions. More importantly, DXT and XFMS can be performed on living cells providing opportunities for hypothesis testing *in vivo*. It is supposed that a virus will have fast and large morphological changes during cell entry with specific staged motions/conformations related to its life cycle. The significance of describing fundamental inter- and intra-particle interactions of a virus is obvious. In this context, approaches utilizing SAXS, DXT and XFMS can detect structural changes with high accuracy and precision.

Virus Crystallography

Jonathan M Grimes, University of Oxford, Oxford, United Kingdom

© 2021 Elsevier Ltd. All rights reserved.

Introduction

Although the first X-ray crystallographic structures of small plant viruses were solved in the late 1970s for tomato bushy stunt virus (TBSV) and Southern bean Mosaic virus (SBMV), the history of virus crystallography extends back to the 1930s and 40s, with the work of Bernal and Fankuchen on the X-ray fiber diffraction analysis on concentrated solutions of tobacco mosaic virus and the work of Dorothy Hodgkin in 1945 on single crystals of tobacco necrosis virus. These early investigations established that many of these viruses were spherical and about 300 Å in diameter. This led to the realization that there was not enough capacity in the viral genomes to code for a single protein sufficiently large to protect the genome and there had to be multiple copies of a smaller capsid protein that would have to assemble to protect the cargo of viral RNA. As all the subunits would be identical, the prediction was that they would have to have identical environments, and this led to the hypothesis that virus capsids would be symmetrical. This was shown to be the case by Caspar in an X-ray study on TBSV which proved that the virus capsid had axes of icosahedral symmetry. Icosahedral particles have axes of 2-fold, 3-fold and 5-fold symmetry and this means that there are 60 copies of the icosahedral building block (or asymmetric unit) that are required for the construction of an icosahedral viral particle. Due to the physical requirements on viruses to enclose sufficient volume to house their large genomes, most viruses contain more than 60 protein subunits and thus the icosahedral asymmetric unit or building block contains more than one chemically identical subunit. Caspar and Klug proposed an extension to the rules of strict symmetry underpinning virus structure with the idea of quasi-equivalence where chemically identical subunits would adapt to similar but non-identical environments. In this model the triangular icosahedral asymmetric unit is further divided into n sub triangles, n being denoted the triangulation number (T number). Although the underlying chemical justification of quasi-equivalence is naive the theory has been extremely useful in interpreting low resolution structural results.

The structures of TBSV and SBMV revealed how 180 copies of the capsid protein had positioned themselves in quasi-equivalent environments – the three chemically identical subunits (A, B and C) were arranged around a quasi-threefold axis in a $T = 3$ structure. A further surprise was the realization that although there was no recognizable sequence similarity between the capsid proteins, they had very similar structures, known now as the “jelly-roll” fold. Not only were the capsid proteins very similar in structure but their architectural arrangement in forming the closed icosahedral capsid was identical, indicating that these two viruses diverged from a common ancestor and were evolutionarily related.

In the 1980s the structures of the first mammalian viruses were solved. These were of picornaviruses, a group of small animal viruses about 300 Å in diameter. Their viral capsids are composed of 60 copies of four viral proteins VP1, VP2, VP3 and VP4, unlike the plant viruses previously solved which have 180 copies of a single protein. The revelations from the structures of rhinovirus, polio virus and foot-and-mouth disease virus (FMDV) were that VP1, VP2 and VP3 all had the same jelly-roll fold and that the fold was identical to that of the capsid proteins of TBSV and SBMV, despite having no obvious amino acid sequence similarity (Fig. 1). Furthermore, these picornavirus proteins were organized in the viral capsid with the same architecture as the plant RNA viruses, forming a pseudo $T = 3$ (or $P = 3$) structure.

Since then the number of structures of viruses has grown exponentially, driven by the developments in the crystallographic methodologies, the technologies of X-ray production at synchrotrons, and of X-ray detectors and by the astronomical advances

Fig. 1 Comparison of the jelly roll capsid proteins of (a) Southern bean mosaic virus (PDB ID 4sbv), and those of Foot-and-Mouth disease virus (5ne4) (b) VP1 (c) VP2 and (d) VP3 colored as a rainbow from the N-terminus to the C-terminus. N- and C-terminal extensions have been removed for clarity.

made in the speed and performance of computing. Although the fundamental principles and ideas behind the crystallographic analysis of a virus particle are no different from those for protein crystallography – the determination of the amplitude and phase of each diffracted X-ray – there is a significant scaling up required of many aspects of the process when compared to a standard crystallographic analysis of a protein. This is due mainly to size – large particles like viruses will crystallize in large unit cells, which means that, for an analysis at a fixed resolution, there are many thousands more reflections that need to be recorded and the density of these reflections on the detector will be equally high. This problem is compounded by the issue that the intensity of these reflections will be many thousand times weaker on average. The weakness of each reflection and the high density and large number of reflections place demands not only on the X-ray sources and detectors but on computer hardware and software.

The seeming structural complexity, might seem problematic in a crystallographic analysis, but the icosahedral symmetry present in virus capsids is of enormous importance providing extremely powerful constraints that facilitate many aspects of the crystallographic analysis (which will be discussed later). In crystals of icosahedral viruses there will be at least 5-fold non-crystallographic symmetry, which gives rise to a 5-fold redundancy in the data. This is because mathematically, a 5-fold axis cannot be found throughout a repeating crystal lattice but can only be present as local symmetry.

Many of the ideas in modern macromolecular crystallography, have been developed and driven by crystallographers having to optimize methods for data collection, by maximizing the signal to noise in the data, as well as developing new software and algorithms as part of their standard toolkit, when confronted by the challenges of the structural analysis of viruses. These include the development of the molecular replacement method and the use of self-rotation functions to determine the orientation of viruses in the crystal unit cell. The fixed relationship between the various icosahedral symmetry axes and the non-crystallographic 5-fold axis means that it is often possible to solve the orientation problem by simple analysis of the diffraction data, in the absence of a model, by use of the self-rotation function. Additionally, the development of the use of non-crystallographic averaging in real space, as well as the use of constraints in the refinement of the model in reciprocal space, was driven largely by the exploitation of the non-crystallographic redundancy that the viral icosahedral symmetry provided. Remarkably Rossmann *et al.* showed that, starting from low resolution experimental phases, high levels of non-crystallographic symmetry provided, through averaging, enough redundancy to allow phase extension, yielding a detailed high resolution map. In the case of FMDV Stuart *et al.* further enhanced the method and were able to obtain an excellent high resolution map without experimental phase information, with minimal (5-fold) non-crystallographic symmetry.

The structural analysis of viruses also led to the development of hybrid methods, particularly the fitting of high-resolution structures of proteins derived by crystallography into lower resolution cryo-EM maps, to generate models, richer in information content, for use in molecular replacement but also that could be tested in functional assays. An example is the structure determination of the Bluetongue virus (BTV) core using a molecular replacement hybrid model generated by the fitting of 260 trimers of the crystal structure of BTV VP7 into a 22 Å cryo-EM map of the BTV core.

Crystallography has also played a fundamental role in structure-based drug discovery (SBDD), as virus enzyme structures allowed the identification of potential inhibitor-binding sites and the optimization of hit molecules against the target structure. During the past decades there have been numerous successful drugs designed using SBDDs against both viral and cancer targets.

One of first landmark examples of SBDD was in the design of pocket factor drugs against human rhinoviruses (HRV). Elucidation of the structure of HRV revealed a canyon formed at the interface of VP1 and VP3. Beneath this canyon, within VP1, there is a hydrophobic pocket that is occupied by a molecule proposed to be a fatty acid. It was shown that this pocket was the likely binding site for a drug previously shown to inhibit picornavirus infections and identification of this site led to the development of anti-virals in collaboration with Sterling Winthrop Pharmaceuticals. Although these anti-virals were highly potent they were not licensed by the FDA due to significant side effects in pregnant women.

In the first few months of the COVID-19 crisis a huge effort has been made across the globe to solve the structures of SARS-CoV2 proteins and use SBDD approaches to develop both anti-viral drugs against validated drug targets, and understand the role of neutralizing antibodies by solving the structure of the F fusion protein complexed to Fab fragments. Although single-particle-analysis (SPA) cryo-EM is now playing a more substantive role with some 109 structures deposited in the PDB database, over 370 structures have been solved by X-ray crystallography, and even for the receptor binding domain of the fusion F spike close to 50% of the structures solved in complex with neutralizing Fabs or nanobodies have been done by crystallography (See “Relevant Websites section”). Alongside SBDD, whole capsid crystallography and the development of recombinant methods for producing virus-like-particles (VLPs) have allowed a more rational basis for the design of vaccines (structural vaccinology), based on improvements in capsid stability and optimization of antigenicity.

The Nitty Gritty: How do you do Virus Crystallography

The basic route to solving a crystal structure is (1) growth of single crystals that diffract to suitable resolution, (2) collection of diffraction intensities from single crystals to give a data set of structure factor amplitudes, (3) initial phase determination, and (4) phase refinement in real and reciprocal space to allow the generation of an atomic model, with minimal errors. Virus crystallography is somewhat more complex but identical in its essentials to protein crystallography. This complexity reflects the large size of even the smallest viruses compared to proteins, which means that there are differences in experimental approaches to deal with the issue of scale. Current methodologies that have been implemented in virus crystallography will be discussed in the following sections:

Targets, Virus Families and Predisposition to Crystallization (Biosafety Levels 2 and 3)

Viruses come in all shapes and sizes – from the simplest virions such as porcine circoviruses with a simple genome coding for the viral replicase and the capsid protein for making the icosahedral viral shell, to the most complex viruses that are larger than the smallest cells; for example, mimiviruses have a virion diameter of about 0.65 μm (some 400 times the size of circoviruses) with a genome encoding >900 genes. Unsurprisingly many of the best studied viruses that directly affect human health and prosperity, are animal and human pathogens, such as human immunodeficiency virus (HIV), measles and now Coronaviruses, but the vast majority of viruses in the biosphere are as yet ill-defined and infect microbes.

At its simplest a virus consists of a genome, which can be RNA or DNA, encapsulated and protected by a protein or proteolipid shell. Viruses are extremely genetically efficient and the use of symmetry, almost invariably icosahedral, helical, or a combination of the two, underpins the structure of many viruses. In viruses that are pleomorphic (with a lipid envelope), there is usually some structural component of the virus, like the matrix protein and the nucleocapsid protein of Influenza virus, that uses multiple copies of a symmetrically arranged protein. Although lipid containing viruses, where the icosahedral protein shell sits on a labile lipid bilayer such as PRD1 and PM2, have been studied by crystallography, the only viruses that have yielded routinely to high resolution single crystal analysis, are viruses that are isometric with highly ordered protein capsids.

Crystallization and Automation (Additives and Aids)

The crystallization of viruses is not any different from that of proteins – in fact given their isometric highly symmetric and ordered capsids one could argue that their tendency to form crystals is unsurprising. All of the caveats and rules surrounding protein crystallization apply to virus crystallization; for a start highly pure, concentrated solutions of structurally homogeneous material are required. One of the reasons why the plant viruses were the earliest viruses studied structurally was that grams of virus could be purified easily from leaf material. It is now routine to use ultracentrifugation with CsCl or sucrose gradients to purify structurally homogeneous capsid particles from genetically homogeneous viruses grown in tissue culture. This purified virus material can then be concentrated up using 100-kDa microconcentrators. The concentrations appropriate for crystallization are usually between 2 and 10 mg/ml, although nowadays a pre-crystallization test (PCT, Hampton) is done to check if the concentration is suitable for crystallization. Over the last twenty years developments in liquid dispensing robotics, driven by structural genomics, have revolutionized automated high-throughput crystallization procedures. Crystallizations are now set-up in 96-well crystallization plates using standard commercial crystallization screening kits (Hampton Research, CA, USA and Emerald Bio-Structures, deCode Genetics, WA, USA), where 100 nl of sample is mixed with 100 nl of precipitant solution.

The reduction of the protein and reservoir solution volumes required for screening crystallization conditions, coupled with improvements in efficiency and reproducibility has effectively replaced hand-pipetting methods for crystallization screening and optimization. The reduction in protein/virus volumes required by a factor of 10 has meant that seemingly intractable targets for crystallization, due to difficulties in producing sufficient purified material, are now tractable. One of the well-known issues that can prevent the growth of well diffracting single crystals is aggregation, sometimes caused by particle instability. If aggregation proves to be a problem, it may be relieved by the addition of detergents, whilst particle stability can be addressed by the use of additives like divalent cations known to interact with the capsid, or changing the pH of the crystallization solution, if the virus is known to be pH sensitive. For viruses, such as ones with an internal lipid bilayer, that are highly fragile and which have a tendency to fall apart when purified, cross-linkers such as glutaraldehyde have been used to stabilize the virus covalently linking proteins prior to crystallization. Even in these problematic cases, for viruses like PRD1 and PM2, it was then necessary to grow the crystals in quartz capillaries to eliminate the mechanical handling of the crystals during data collection. The final step to produce well diffracting crystals was to then dehydrate the crystals in the capillaries with high-molecular-weight PEG, effectively reannealing the crystals in-situ.

Crystal Handling and Cryoprotection (Notes for Enveloped and Non-Enveloped Viruses)

Whilst it is perhaps not surprising that robust spherical virus capsids crystallize, it is astonishing that crystals held together by only a few noncovalent interactions, are so beautifully ordered. Virus crystals tend to be more fragile than protein crystals, due to the relatively smaller surface area to mass ratio of the interfaces that hold the crystal together. Whereas protein crystals are cryogenically cooled to liquid nitrogen temperatures prior to data collection, the cooling of virus crystals is still uncommon. The major problem is that the mosaic spread of crystals tends to increase on cooling, meaning that the spot size of the recorded reflections becomes larger, frequently resulting in the overlap of reflections. The traditional approach for mounting virus crystals was to use the method of sealing hydrated crystals in capillaries – this was the standard method for protein crystallography prior to the now routine method of cryogenically cooling of crystals in loops. Due to disease security issues this method also had the advantage of being suitable for crystals of highly contagious viruses, like FMDV.

An implication of room temperature (RT) data collection is that a large number of crystals are often required to collect sufficient data to solve a virus structure. Thus, for challenging projects such as bluetongue virus (BTV) more than 1000 crystals were needed to solve the structure.

Data Collection (In-House and Synchrotron) and Automation

It was commonplace for previous generations of macromolecular crystallographers to have their own in-house X-ray sources for data collection. For virus data collection this was a laborious process requiring the careful focussing of the beam and many hours of exposure of the crystal to collect a single X-ray diffraction image (constituting a tiny fraction of a complete data set). However, one of the fundamental drivers that has powered the revolutionary advances in macromolecular crystallography over the last 30 years has been the availability of synchrotron radiation sources to macromolecular crystallographers. In the 1980s access to second generation synchrotrons, like Daresbury (UK), greatly speeded up and improved the process of data collection, revolutionizing how diffraction data were collected not only for viruses but also for all crystals of macromolecules by bringing the streets of Baltimore to the synchrotron with the introduction of the so-called “American Method” of data collection (shoot first, ask questions later), now rebadged as serial crystallography. Historically, as part of the data collection process, the crystal was set into a known orientation relative to the detector axes by a series of short X-ray exposures. Virus crystals are highly sensitive to intense synchrotron X-ray beams and so are normally only aligned optically before data collection, meaning that the auto-indexing algorithms that are now routine had to be developed to analyze the diffraction pattern. Further gains in crystal lifetime and signal-to-noise ratio were achieved by tuning the wavelength to below 1 Å (compared to 1.5 Å from in-house sources). Analysis by Fry *et al.* 1999 demonstrated that this method of data collection, where crystals are randomly orientated in the beam, is surprisingly efficient, and for high symmetry space groups like I23, a 64% complete data set can be collected from only 8° of data.

Historically in the structure analysis of small picornaviruses, like human rhinovirus (HRV) or FMDV, for a 3 Å resolution data set, the crystal would be oscillated in the beam for 0.3–0.5°, for several seconds, depending on the lattice properties and the image would be recorded on X-ray film, requiring significant manual intervention in “dark rooms” to develop the films, prior to scanning and image rasterization.

Further gains were made with the development of third-generation sources such as the European Synchrotron Radiation Facility (ESRF) in France and Diamond Light Source in the UK. Such synchrotrons provide highly brilliant, tuneable, and parallel X-ray beams that allow the collection of densely-packed but weak diffraction data – X-ray beams that are ideally suited optically to the large unit cells of virus crystals. As an aside it is interesting to note that the power of synchrotron beams fueled the explosion in cryo-crystallography which allowed the hundred-fold increase in crystal lifetime to be fully exploited in modern macromolecular crystallography.

These highly intense beams have meant that exposure times have been reduced by at least an order of magnitude. This in turn has driven the development of faster X-ray detectors, such as the Dectris pixel-array detectors which match the speed of data collection and this increase in speed has in turn driven the development of automation and the remote control of beamlines. For cryo-crystallography of macromolecules these developments have brought the time to collect a complete 360° data set down to a few seconds.

For room temperature analysis bottle necks remain in the logistics of presenting crystals to the X-ray beam. Over the past ten years, the installation of high-precision goniometers at beamlines I03 and I24 at Diamond Light Source capable of holding crystallization plates and presenting each of the crystallization drops to the X-ray beam, has allowed the rapid collection of in-situ room temperature data (Fig. 2). Collecting diffraction data in-situ eliminates the need to mount virus crystals in capillaries, a process that can often result in physical damage to the crystals, and maintains the integrity of virus crystals which are often very fragile. An additional consideration in virus crystallography is that in-situ analysis in sealed plates, as opposed to collecting data from crystals in open loops with the inherent issues of disease-security, provides a safe alternative for these pathogenic samples.

As an example of the latest state of the art, the structures of bovine enterovirus 2 (BEV2), enterovirus 71 (EV71) and FMDV virus like particles (VLPs) have all been solved on I24, from crystals grown in CrystalQuick X plates. These plates reduce the background by around a factor of 2.5, compared to Greiner CrystalQuick SW plates. Data were collected on a Pilatus 6MF detector operating in shutterless mode at 294K, the ambient temperature of the beamline, with individual frames of either 0.1° or 0.05° and exposure times of typically 0.1 s or less, enough to ensure the data were of sufficient strength for relatively routine processing. Under the regime described here the crystal life-time was typically 0.4 s. In the example of BEV2, a beam size of 20 × 20 µm allowed 76 exposed positions from 26 crystals, resulting in a 66% complete data set to 2.1 Å (Fig. 2).

Many synchrotrons now have automated pipelines for data analysis and data processing is now standard for crystals with large unit cells. To those who have not collected and analysed RT data, there will be a large number of partially recorded reflections that cannot be summed with their complementary parts on successive images (unlike cryo-data collection) and for these data the knowledge of the fraction of each partial reflection recorded allows the observed intensity to be scaled up to the value it would be if the reflection were fully recorded.

Structure Solution and Model Building

Once diffraction data have been gathered the next stage in the structure analysis breaks into two stages, initial phase determination and then subsequent phase refinement and extension.

Phases estimation requires defining the orientation and the position of the virus particle(s) in the crystal cell. This information is essential for phase refinement. Because of the inevitable non-crystallographic redundancy (a minimum of 5-fold) and the fixed relationship between the various icosahedral symmetry axes, it is often possible to solve the orientation problem by analysis of the diffraction data in the absence of a model, usually by use of a self-rotation function.

Fig. 2 Data collection on virus crystals. (a) The sample environment at beamline I24 for in-situ X-ray diffraction. (b) Images of a crystal of BEV during an X-ray diffraction experiment using a 20 μm beam size. (c) Typical diffraction pattern from a crystal of BEV with an exposure of 0.1 s and an oscillation on 0.1°.

Phases need to be derived for each of the measured reflections before electron density maps can be calculated, and these are usually generated by molecular replacement with a model structure, perhaps derived by cryo-EM. The non-crystallographic symmetry provides powerful phase constraints so that even a poor model, with poor phase estimates can be improved dramatically by the cyclic imposition of icosahedral symmetry. The procedure is relatively straightforward. The non-crystallographically related portions of the electron density map of the virus are averaged, and the regions not defined as virus are flattened to an average electron density value. This effectively cleans up the map, which is then back-transformed to generate improved calculated amplitudes and phases. The calculated structure factors are then recombined, suitably weighted, with the observed amplitudes and a new map is calculated. The procedure is then iterated to convergence. If the initial model is particularly inaccurate it may be necessary to solve the structure at low resolution, and then use the constraints in real space to extend and refine the phases to the resolution of the data.

If phases are to be extended, the map is back-transformed to a slightly higher resolution than it was calculated at, which provides phase estimates (albeit crude) to this new limit, which can then be fed back into the cyclical procedure. There are features in the process that are not standard and require thought, such as adding in calculated data for missing observed

amplitudes, and careful analysis of the averaging and solvent masks, which will need to be recalculated at intervals during the phase refinement and extension.

Once the real space phase refinement has converged, the map should be of sufficient quality that the polypeptide chain can be readily interpreted and a model rapidly build for the icosahedral asymmetric unit. Standard crystallographic refinement packages can then be used to refine the model against the data, normally imposing strict non-crystallographic constraints to maximize the observation to parameter ratio.

Understanding Evolution through Structural Anatomy

The structural analysis of the first plant and mammalian viruses demonstrated that the capsid protein fold and arrangement of the capsid subunits was conserved between the viruses although they belong to different families and infect different hosts. These striking similarities were assumed to signify descent from a common ancestor, but it was acknowledged at the time that it may reflect convergence, from separate ancestors, to a suitable stable capsid. Although comparison of genome and protein sequences allows the comparison of closely related viruses this approach becomes meaningless as sequences diverge. The observation that structure changes more slowly than sequence (due to the constraints of chemistry) provided a basis for comparison of seemingly unrelated viruses.

The principle when comparing structure, as with classical anatomy, is that similarity in structure can be taken as evidence of homology. Features such as atomic coordinates, chain direction, secondary structure similarity, topological similarity and loop length similarity are built into the comparison such that the argument for homology becomes compelling.

As the number of virus structures solved increased, it became apparent that structure could be used to uncover evolutionary relationships between seemingly diverse viruses, and that these viruses had an ancient history, spread across the 3 kingdoms of life.

A key observation was made by Burnett *et al.*, when they solved the PRD1 major coat protein structure and showed that its closest structural relative was the coat protein of adenovirus. This work revealed that the major viral capsid protein was a trimer with a common coat fold (the so-called double-barrel) arranged in hexagonal capsomer structures which provided direct evidence linking the bacterial virus (PRD1 infecting gram-negative bacterial hosts) to a human pathogen (the dsDNA adenovirus).

Two examples which provide further conclusive evidence for this are the capsid protein of sulfolobus turreted icosahedral virus (STIV), an archaeal virus, which was shown to have the same fold and architecture as the capsid proteins of PRD1 and adenovirus. In addition, the human pathogen Herpes simplex virus was shown to be structurally related to the bacteriophages HK97, P22 and T4, both in terms of capsid architecture but also in the molecular portals that package the genome into the preformed viral capsid.

Since then it has become widely accepted that the comparison of coat protein structure and virion architecture can provide fundamental insights into the evolutionary grouping of viruses previously considered to be unrelated, although further work is needed to improve the statistical basis and the robustness of the computational procedures. It is clear that icosahedral viruses fall into a small number of lineages, the members of which infect all 3 domains of life, but for enveloped viruses without a defined capsid protein, it is unclear what aspects retain an evolutionary signature.

Synergies

Our understanding of the biology of viruses through structure is best addressed by a range of different techniques that reveal both the static and dynamic aspects of the virus and on different scales.

The resolution revolution in cryo-EM now means that the one can obtain atomic information by SPA of flexible assemblies but also now, with cryo-electron tomography and in-situ imaging, structural details of viruses and viral assemblies within cells. With the developments in FIB milling, to produce thin lamella of a suitable thickness to allow electrons to penetrate through the sample, it is feasible to get to sub 10 Å resolution, where atomic models derived by crystallography and SPA cryo-EM, can be refined as rigid bodies into cellular maps. A recent beautiful example of this is the structure of an assembly intermediate of a mammalian dsRNA orthoreovirus, solved at a resolution of 5.6 Å, by imaging of cryo-preserved infected cells, which revealed a striking similarity with an assembly intermediate of a dsRNA bacteriophage, suggesting a common mechanism of viral assembly.

Alongside EM, soft X-ray imaging when combined with cryo-structured illumination microscopy (cryo-SIM) provides a powerful technique to image whole cells (unlike EM), due to the penetrative quality of X-rays, and the potential to correlate cellular remodeling that occurs in response to viral infection, with fluorescently labeled viruses or other biomarkers. These techniques combined with live cell imaging can provide orthogonality to the molecular detail by providing temporal information on the biology of viruses.

At the more extreme end of what is now possible in diffraction, serial femtosecond crystallography (SFX) at an X-ray free-electron laser (XFEL) now provides the opportunity, due to the extreme brightness of the X-rays, to image viral crystalline arrays within cells as well as the possibilities of capturing stages in viral disassembly.

Vaccines, Anti-Virals and Therapeutics

Structural biology has played an increasing role in the development of vaccines and anti-virals. Conventional vaccines have had a radical impact in improving human health, and are one of the most effective tools for the prevention of infectious diseases. The

discovery 200 years ago that vaccinia virus could be used to protect people from small pox, has led to the eventual eradication of the disease, and the development of vaccines that protect against polio and measles infections.

The current vaccines on the market are based largely on inactivated or attenuated live virus, with some recent developments in virus-vector vaccines. Whilst these live attenuated or inactivated vaccines have been successful in protecting people from infectious diseases there are significant drawbacks such as the cost and risks associated with the production of large volumes of highly pathogenic viruses under high biosafety containment along with the significant risk of attenuated forms reverting back to pathogenic forms. Traditional vaccine development is a long complex process and can take 10–15 years before the vaccine is approved for use. The Ebola outbreak in 2014–2016 in West Africa and the COVID 19 pandemic of 2020 highlighted the need of different approaches where targeted vaccines can be rapidly produced in sufficient quantities.

The large amount of knowledge now available on the three-dimensional structure of viral capsids and viral glycoproteins provides tremendous opportunities for structure-based vaccine design, based on the rational engineering of the antigenic and biophysical properties. The adaptive and innate immune systems have evolved to recognize highly repetitive structures, such as viral capsids and bacterial flagella rather than soluble antigen, and it is apparent that capsid integrity, and stabilization of antigenic forms of viral proteins is key to generating a protective immune response.

Two approaches to vaccine design that have benefitted from structural data are of viral vectors and the use of viral-like-particles (lacking any genomic material). Viral vectors are a non-pathogenic or non-replicating virus which is used as a vector to deliver the gene, encoding the viral antigen, into the host cell, where the antigen is expressed and induces an immune response. A very current example of this is ChAdOx1, currently under trial as a vaccine against SARS-CoV-2 which is a harmless chimpanzee adenovirus encoding the gene for the surface spike protein of SARS-CoV-2. This spike protein is expressed on cells in the immunized patient and the hope is that the immune response generated against this antigen is sufficient for protection. One problem that can occur is that the presenting antigen may not be sufficiently immunogenic. An example of this is the vaccine development against Respiratory syncytial virus (RSV), which is an enveloped RNA virus second only to malaria as a cause of infant mortality worldwide. Antibodies against RSV from infected patients mainly target the trimeric F surface glycoprotein of RSV which drives the membrane fusion that occurs on viral infection. However, F is metastable and rapidly converts to its post-fusion form which induces the production of antibodies that offer less protection against the virus. The structure of RSV F allowed the rational design of mutations that stabilised F in its prefusion form. Initial experiments using the stabilised F as a vaccine showed that it elicits antibodies that target prefusion epitopes. Recently the design of self-assembling nano-particles, where the stabilised F proteins are displayed on an icosahedral scaffold, has been shown to induce a 10-fold higher response of neutralizing antibodies compared to the protein alone.

An example of the development of VLPs in vaccine design is FMDV. FMDV is a highly contagious disease of cattle and sheep and the cost of outbreaks can be huge due to the requirement to slaughter infected animals. In the outbreak of 2001 over 6 million animals were slaughtered at a cost in excess of £8 billion. Current vaccines for FMDV are based on inactivated virus, and vaccine production is expensive and technically challenging. The vaccines are thermally unstable, and the capsids rapidly breakdown into pentamers which are not immunogenic. FMDV vaccines thus require a cold chain due to the warm climate in those areas of the world where they are used. There are also difficulties in distinguishing vaccinated animals from infected animals which has significant economic implications, due to restrictions that are imposed on the movement of infected animals. Development of novel vaccines for FMDV has been based on the rational introduction of mutations to increase thermostability. For VLPs a disulfide across the icosahedral 2-fold axis between adjacent pentamers effectively locks the VLP capsid, whilst for FMDV O and SAT2 serotype viruses which are unstable vaccines, the introduction of a hydrophobic residue at the same position conferred increased thermal stability, and retained immunogenicity over long term storage unlike wild type inactivated virus which rapidly becomes non-protective when stored (Fig. 3). Recent work on enteroviruses has revealed a positively-charged surface depression at a protomer interface on the capsid surface that is bound by glutathione known to be essential for the assembly of many enteroviruses. This depression has been identified as potentially druggable and amenable to SBDD (Fig. 3).

Whilst this review has focussed on whole capsid crystallography, there have been numerous successes in the rational design of anti-viral inhibitors targeting functionally important proteins of significant human pathogens such as HIV, Hepatitis C and Influenza virus. The rationale being that if you can design small molecules that inhibit these conserved mechanisms then the viral lifecycle is disrupted. Some of the earliest successful examples of SBDD were antiviral drugs that targeted the viral neuraminidase of Influenza virus (oseltamivir, zanamivir) and the peptide-based inhibitors of the HIV protease. Other validated viral targets include proteins involved in replication of the viral genome, such as integrases, methyltransferases as well as host cell factors.

These successes were followed by the development of nucleoside inhibitors (NI) and non-nucleoside inhibitors (NNI) against the reverse transcriptase of HIV (HIV-1 RT) – which is now one of the most successful approaches for the treatment of HIV infections. NIs are incorporated into the newly synthesized genome by RT, and prevent further incorporation of incoming nucleotides, acting as obligate chain terminators. The NNIs act by binding to or close to the active site of RT and blocking replication. RNA dependent polymerases are attractive targets for anti-virals and successful drugs have been developed against human pathogens such as Hepatitis C virus and Influenza virus. Recently new compounds targeting the influenza virus polymerase complex have recently progressed to or through late phase clinical trials. The polymerase complex of influenza viruses is a heterotrimer and both replicates the viral genome as well as initiating transcription using short capped RNAs snatched from RNA polymerase II (Pol II). The polymerase has both a cap binding domain as well as an endonuclease domain which capture cellular mRNAs and subsequently cleave the mRNAs 10–12 nucleotides from the cap. This multifunctional enzyme is an attractive target for drug development and recently a number of drugs have been developed that target the different active sites – Pimodivir blocks cap binding, Baloxavir inhibits the cap-dependent endonuclease

Fig. 3 Structural analysis of FMDV A22 empty particles and BEV. (a) Electron density maps for FMDV A22 (left and zoomed up middle panel) and the A22-H2093C mutant (right panel) showing the disulfide bond forming across the icosahedral 2-fold axis. (b) Structure of BEV capsid with one of the bound glutathione molecules highlighted and in the right panel the 15-fold NCS-averaged electron density for the glutathione.

activity thus inhibiting RNA cleavage and Favipiravir acts as a purine nucleoside which is recognized as an alternative substrate by the viral polymerase resulting in errors during viral RNA synthesis. The current anti-virals in clinical use or in late clinical trials target functionally key steps in the viral lifecycle, but unfortunately due to the high error rates in RNA virus replication, escape mutations drive drug-resistance in HIV, Influenza and other RNA viruses. Hence there is a great clinical need to discover additional strategies and targets as part of the development of novel antivirals.

Future Outlook

We have come a long way over the last thirty years since the first high resolution crystallographic analyzes of virus structures. Although now routine, these pioneering efforts were laborious and required innovative approaches to both collection of the data and the subsequent downstream analysis, which at the time was computationally demanding. The developments in technologies in cryo-EM means that for many samples, where there is heterogeneity in both conformation and composition, it has become the method of choice for structural analysis. However, crystallography, by selecting out a particular single conformation (or several with NCS) in the crystal, very often gives higher resolution structures than cryo-EM where most particles imaged must be thrown away or classified into a plethora of conformations. For structural analyzes of many of these fragile macromolecular complexes we will see hybrid models produced by the fitting of high-resolution structures of fragments or domains, derived by crystallography, into lower resolution cryo-EM maps produced by SPA or tomography. Looking into the future where imaging will take us to structural cellular biology these models will be key to building up an understanding of the complete virus life-cycle – crystallography will still have a key role to play.

Acknowledgments

I would like to thank Dr Harkiolaki and Dr Fry for critical reading of the manuscript, and Drs Duyvesteyn, Ren and Axford for help with production of the figures.

Glossary

CLEM Correlative Light and Electron Microscopy, a technique that consists on acquiring fluorescence microscopy micrographs and normally Cryo Electron Tomography to obtain data that is complementary from both techniques.

EM-CCD camera Electron Multiplied Charged Coupled Device sensor, Integrated circuit onto a silicon surface with light sensitive pixels. When photons are detected in the semiconductor oxide interface they generate charge read by electronics and translated into a digital image. Ideal for low intensities and noise characterization.

FCCS Fluorescence Cross-Correlation Spectroscopy, is a derivative from FCS that utilizes two channels to cross-correlate fluorescence fluctuations of two fluorescent particles that might co-diffuse together through a confocal volume. The technique assumes that if two particles co-diffuse together through a confocal volume these particles are interacting and therefore the technique is useful to detect protein-protein interactions in live cells at low concentrations.

FCS Fluorescence Correlation Spectroscopy, is a microscopy technique that employees the fluorescence fluctuations resolved in time coming from fluorescent particles diffusing through a confocal volume. A correlation analysis is performed on the fluctuation of the fluorescence intensity providing information on the concentration of fluorescent particles and their diffusion coefficient.

FLIM Fluorescence Lifetime Imaging Microscopy, a microscopy technique able to recover the time that an electron resides in the Lowest Unoccupied Molecular Orbital (LUMO) before relaxing down to the Highest Occupied Molecular Orbital (HOMO) through radiative (emitting a photon) and non-radiative pathways (emitting heat). The inverse of the kinetic constants regulating these process is the mathematical definition of the Lifetime for a particular fluorophore.

Fluorescent Proteins Ever since the discovery in the 1960s of the green fluorescent protein (GFP), composed of 238 amino acids and able to fluoresce when exposed to blue light (~488 nm) other variants and colors have been derived or discovered from other organisms. There is a rich

palette of different genetically encodable fluorescent proteins with attractive properties for imaging from the blue to the far-red.

FRET Forster Resonance Energy Transfer, a phenomenon that consists on the non-radiative emission of energy between two dipoles situated at the right distance (~10 nm), the right relative orientation and the right spectral properties between the donor and the acceptor of non-radiative energy (the donor absorption spectral must overlap with the acceptor's emission).

N&B Number and Brightness, is a correlation technique based on moment analysis to measure the average number of fluorescent particles diffusing through a confocal volume (that can be scanned to create an image) and the molecular brightness (in counts per molecule per unit time) of each fluctuation trace (i.e., pixel by pixel when analyzing a whole stack of images).

Pseudovirus A recombinant particle that contains its core and envelope proteins from different viruses. They may also contain altered or modified genes so that they will be unable to produce surface proteins on the infected host.

Quantum Dot A nanometer sized semiconductor crystal with distinctive conductive properties and able to fluoresce with high intensities.

sCMOS camera scientific Complementary Metal-Oxide-Semiconductor, these image sensors offer low noise, big field of view, high quantum yield and high speed. CMOS circuitry dissipates less power than other logic families of sensors.

Single Molecule Localization Microscopy A super resolution technique that consists of isolating single emitters and fitting the corresponding point spread function with a mathematical model that determines its location with a precision limited by its intensity (number of photons).

Stokes shift Difference between the absorption and emission fluorescence spectra for the same electronic transition caused by a loss of vibrational energy when electrons relax from the LUMO to the HOMO (see above).

Synthetic Fluorescent Dyes A fluorescent chemical compound that re-emits light upon exposure to excitation source. Fluorophores contain several combined aromatic groups.

Introduction

Live-cell imaging of virus-infected cells has served as an innovative platform to revolutionize and transform our understanding of virus infection and pathogenesis. But it was centuries after the visualisation of microorganisms with Anton van Leeuwenhoek's microscope in the 17th century, and decades after Abbe's optical diffraction limit of light microscopes was postulated, that

nanometer-scale virus particles were finally resolved. This revolution in virology was powered by imaging systems harnessing electromagnetic waves (i.e., electron microscopy) to visualize virion structure and the early and late stages of their life-cycles. In parallel, groundbreaking advances in light microscopy, in particular fluorescence and quantum dot labeling, combined with single-particle tracking (SPT) and quantitative spectral imaging approaches (e.g., FCS, FCCS and Number and Brightness), advanced numerous studies probing virion structure, entry and pathogenesis. Importantly, virology investigations now rest on the complementarity between electron and light microscopy approaches, where light microscopy sensitivity and resolution can now border single-molecules and 1 nm scales, respectively.

This cohesiveness between light- and electron-based microscopy platforms in answering critical questions surrounding virion structure, entry and pathogenesis are exemplified by recent advances in our understanding of many viruses. Human Immunodeficiency Virus (HIV-1) has been extensively studied and the application of different microscopy approaches has allowed us to understand many aspects of its pathogenicity and the availability of genetically-encoded fluorescent proteins (FPs) tagged to proteins of interests has yielded key insights regarding its lifecycle, including intracellular trafficking, nuclear import and capsid oligomer formation and budding in live single cells. Because of the rapid development of these sophisticated fluorescent probes and the ability to tag various different viral components, the detection of and ability to track single virus particles (i.e., SPT) in live cells has also provided a mechanistic understanding of key steps of virus infection, especially virus entry. In particular, SPT has created intense discussion concerning HIV-1 entry mechanisms (i.e., plasma membrane fusion versus endocytosis), and has been shown to differ in part according to the host cell studied. Additionally, our group utilized fluorescence fluctuation approaches (i.e., N&B) to uncover the evolution of the HIV-1 receptor (i.e., CD4) and coreceptor (i.e., CCR5 or CXCR4) stoichiometry during virion entry with single molecule spatial and temporal resolution. These studies are examples of how investigators are currently creating platforms to dissect interactions between host and virus-specific factors with high spatio-temporal resolution. In parallel, cryo-electron tomography (cryo-ET)-based methods have been able to link these live, dynamic observations between the virus and host with high-resolution structural data. For example, after cryo-ET was used to visualize the surprisingly few trimeric Env glycoproteins in their native environment on the virion surface, it was soon revealed that these glycoproteins cluster in an “entry claw” like fashion that is maturation-dependent, corroborating quantitative live-cell light microscopy studies.

In this article, our goal is to summarize the methodologies we believe are most useful to uncover mechanisms of virus entry, pathogenesis and structure in both live cells and tissue with single molecule resolution. In particular, we believe that recent innovations in virus labeling, SPT, quantitative spectral imaging and multiphoton microscopy will lead to unprecedented advances in virology studies at the single-molecule level in physiologically-relevant models, such as tissue explants, organoids and in vivo imaging. In addition, advances in cryo-ET and its role in advancing our understanding of virus structure and its influence on viral protein function will be discussed with a particular emphasis on HIV-1. Finally, we conclude with a brief discussion on the use of correlative live-cell and cryo-ET approaches to visualize and understand dynamic virus-host interactions during entry. For a comprehensive summary of common imaging modalities, see [Table 1](#).

Virus Labeling

The use of different methods to label enveloped and non-enveloped viruses is crucial for light microscopy. Overall, two approaches have been employed to label viruses during the last two decades. Either one or more viral proteins can be fused with a fluorescent protein (FP) or direct chemical labeling is employed utilising small dye molecules such as cyanine or Alexa dyes, or lipophilic dyes for enveloped viruses such as DiD or DiO.

Since the discovery of green fluorescent protein (GFP), many variants have been developed utilising directed evolution techniques that present attractive features in terms of emission spectra (ranging from the blue to the far red), brightness, quantum yield and photostability. Importantly the pKa of different proteins can be employed to measure pH, and these measurements can be very accurate using FRET-based biosensors incorporated in single viruses such as pHlameleons. The process of fusing a FP into a viral protein does not drastically differ from simple cloning employed to label a protein of interest. The corresponding FP is incorporated into the open

Fig. 1 Labeling of HIV-1 virions to ascertain the point of fusion via single virus tracking. Cartoon depicting double labeled HIV-1 mature virions with a strategy that identifies the point of fusion: membrane versus endosomal. DiD lipophilic dye (far red) stains the viral membrane and the capsid is labeled in the Gag (Gag-GFP). In mature viruses, cleavage releases the GFP (green fluorescent protein) that resides in the matrix of the virus. When hemifusion occurs the far red dye DiD is diluted in the plasma membrane of the host (yellow signal shifts to green). Subsequently, full fusion and pore opening allows the cleaved GFP to be released in the cytosol (green signal disappearance). If the primed double labeled virus is internalized via endocytosis and fusion occurs within endosomes, the DiD lipophilic dye redistributes around the endosomal lumen and only when fusion occurs there is a shift in color from yellow to red.

reading frame of the target viral protein, for example in the case of retroviruses Gag is a common target for FP labeling (Fig. 1). Nevertheless, the detection of single viruses requires large numbers of labeled viral proteins, and depending on the sensitivity of the light microscope employed, one can resolve single viruses when labeling a few Env glycoproteins or hundreds of cleaved nucleocapsid proteins, such as Vpr in the case of HIV.

Chemical labeling can also be employed to label virus structures. The type of bonds created between the dye and the viral protein can be covalent or non covalent. Thus capsids of non-enveloped viruses are often labeled with amino-reactive dyes. Another type of labeling is related to cell-permeable biarsenical dyes that specifically attach to viral proteins with tetracysteine peptide sequences. Importantly, the use of antibodies is not recommended as they might interfere with viral protein function before or after binding. In that regard, it will be interesting to witness how nanobodies can be employed to label viral proteins and how they affect their function, as nanobodies were utilised to target the HIV-1 Env in our recent study on HIV-1 entry.

Advanced Light Microscopy Approaches

Quantitative light microscopy has been employed to understand with molecular detail the life cycle of many viruses such as HIV, Ebola, Avian Sarcoma and Leukosis Virus, or Vesicular Stomatitis Virus. Light microscopy is a particularly attractive technique for virology as it can resolve, with single molecular resolution, the temporal dimension of different stages of infection. Importantly, the combined use of quantitative spectral imaging such as fluorescence lifetime imaging microscopy with single virus tracking, offers the opportunity to recover on-line information of single virus entry and the particular response of the host molecules that

are modulating this process. Here, we focus on advanced light microscopy techniques with considerable potential: real-time single virus tracking, spectral imaging and how to correlate these approaches with light super-resolution techniques and cryo-electron tomography. We have decided not to talk about super-resolution light microscopy as recent literature focuses on this aspect in the context of virus entry.

Real-Time Single Virus Tracking in Live cells

Real-time single virus tracking (SVT) has been extensively employed for many viruses during the last two decades. Indeed, high temporal resolution allows researchers to track the different stages of the infection process for single viruses. In a seminal work utilising this technique, Seisenberger *et al.* studied the infection pathway of Adeno-Associated Virus (AAV). The authors covalently attached Cy5 to viral proteins analyzing thousands of trajectories of single AAV-Cy5 particles in living HeLa cells. The authors established that single particles were able to diffuse randomly outside the cell; this slowed down when AAV approached the cell surface and around 13% of the particles internalized via endocytosis. Furthermore, this SVT-approach showed that endosome diffusion was directed toward the nuclei and that virus particles within the nucleolus underwent directed motion and were unidirectional. This report on the application of SVT on AAV opened up a number of possibilities to study the molecular environment and entry pathways of many other viruses. This work was carried out with wide field illumination and a CCD camera, an affordable set up that has since evolved with developments in optics and detection units (e.g., scientific CMOS and back illuminated CMOS cameras).

Combining the right strategy for virus labeling with SVT has proven to be beneficial to establish the point of entry and fusion for many other viruses. In a seminal paper describing the use of SVT to understand virus entry, Melikyan *et al.* examined individual retroviral fusion events. Avian Sarcoma and Leukosis Virus (ASLV) was labeled with a lipophilic dye and palmitoylated enhanced yellow fluorescent protein (YFP) incorporated in the inner leaflet of the viral membrane. Melikyan *et al.* found that hemifusion and small pore formation are key intermediates of ASLV fusion in CV-1 cells. In another paper, Padilla-Parra *et al.* took advantage of the combined use of FRET-based biosensors to quantitatively measure pH and SVT to detect single virus fusion (Gag-mCherry). This approach allowed the quantification of the pH sensed by individual ASLV virus particles during priming, endocytosis and fusion in live CV-1 cells. For the majority of ASLV virus tracked to the point of endosomal fusion, fusion occurred on average at 6–6.1 pH units. This article demonstrated the usefulness of combining SVT with FRET-based biosensors incorporated in single retroviruses. As mentioned above, there are now reports utilising SVT to dissect the point of entry for many other viruses. For example, recent applications of SVT allowed the detection of entry and fusion of HIV in macrophages via endocytosis as opposed to T cells that occurred on the plasma membrane.

Quantitative Spectral Imaging

The use of spectral imaging applied to virology offers the possibility to obtain time-resolved molecular information for a number of host-virus interactions. Various spectral-based techniques such as Fluorescence Lifetime Imaging Microscopy (FLIM), Number and Brightness (N&B) (Fig. 2) and Fluorescence Correlation Spectroscopy and derivatives (FCS) have been employed. In a recent report, our group combined SVT with N&B to resolve the time-resolved stoichiometry of HIV-1 pre-fusion reaction. We employed HIV-1 pseudoviruses labeled with Gag-mCherry exposed to live COS-7 cells co-expressing CD4 and CCR5 or CXCR4 coreceptors labeled with mTFP1 and mOrange respectively. The HIV-1 Env pre-fusion reaction was shown to consist of a three-step mechanism with different stoichiometry (i.e., number of CD4 and coreceptors engaged in the fusion complex) depending on HIV tropism. In another report our group also demonstrated the role of dynamin during HIV-1 entry and fusion by combining functional assays for HIV fusion with FLIM and N&B in live TZM-bl and primary CD4⁺ T cells. FLIM was employed to detect Förster Resonance Energy Transfer (FRET) in TZM-bl cells co-expressing dynamin labeled with GFP and mCherry. The addition of HIV pseudoparticles decorated with different envelope proteins (either VSV-G or JR-FL) induced a different response in the extent of dynamin interactions suggesting a different role for dynamin during entry for HIV and VSV. These results were confirmed when combining fast Total Internal Reflection Fluorescence Microscopy (TIRFM) with N&B with TZM-bl cells expressing Dynamin-GFP, where it was illustrated that the oligomeric state of dynamin differs when the cells are exposed to VSV-G or JR-FL pseudoparticles. Further experiments based on co-localization, SVT and cell-cell fusion confirmed the role of dynamin during HIV fusion, where it was shown that dynamin stabilizes the fusion pore during HIV entry with a low oligomeric state, (i.e., a tetramer). These results were confirmed by Aggarwal *et al.* utilising functional assays and SVT. Spectral imaging has been traditionally applied almost exclusively in cell biology. Nevertheless, there are a number of groups combining the power of these approaches to better understand different stages of the virus infection cycle. We are convinced of the general usefulness of these techniques when elucidating virus entry.

Multiphoton Imaging

Two-photon microscopy is a platform rooted in nonlinear interactions between photons and matter, in which two photons from an ultrashort, pulsed infrared laser each deliver approximately one-half of the energy necessary to excite the same fluorophore “instantaneously” to its lowest unoccupied molecular orbital. Combined with a high numerical aperture, an extraordinarily high photon flux is delivered to a fractional volume of the specimen. Furthermore, because a multiphoton absorption event is only likely at the focal point in the excitation volume, nonlinear photon interactions exist only in the focal plane. Moreover,

two-photon decay processes occur identically to a single-photon absorption event, leading to a similar fluorescence profile, albeit an “inverse” Stokes shift as the excitation is completed by infrared light.

In addition to two-photon microscopy, other multiphoton microscopy platforms can be utilised for label-free and non-invasive functional imaging in organoids and tissue, such as second harmonic generation (SHG), third harmonic generation (THG) and three-photon microscopy. Briefly, in three-photon microscopy three photons are absorbed by the fluorophore to achieve the excited state and in SHG and THG, high photon densities are optically scattered such that they combine to form a single photon with double the energy of the incident photon in either spatially-ordered or heterogenic specimens, respectively.

Most multiphoton modalities utilise near-infrared excitation, taking advantage of either endogenous fluorescence, SHG or THG to image biological phenomena in living tissue with high spatiotemporal resolution. For example, endogenous fluorescence is often the result of the excitation of metabolic redox reaction cofactors NADH, NAD(P)H or FAD. These molecules may absorb UV light and subsequently fluoresce; however, this is often photo-toxic for the living tissue examined. Therefore, by combining multiphoton microscopy with imaging (FLIM), researchers may be able to specifically study NAD(P)H and FAD dynamics to report on the metabolic redox activity of individual cells within tissue with exceptional environmental sensitivity. In particular, the fluorescence lifetimes of NAD(P)H and FAD change according to their environment; that is upon protein binding during the electron transport chain (ETC). Therefore, label-free lifetime imaging these molecules informs the ratio of free and bound NAD(P)H, in addition to the redox states of FAD/FADH₂ and NADH/NAD⁺ of single cells within the tissue. This information is in turn, related to the glycolytic and the metabolic states of the cells, which can change during and influence the course of viral entry and infection.

Excitingly, this technology has been employed in different biological and pathological contexts. For example, two-photon FLIM was recently employed in hepatocytes to demonstrate how hepatitis C virus core protein D2 decreases free and bound NAD(P)H lifetimes with a concomitant increase in free NAD(P)H levels, indicative of D2-induced disruption of the ETC, subsequently triggering a shift in glycolysis and lipid biomass accumulation in human hepatoma cell line Huh-7. Our group recently found using this approach the metabolic shift of primary T cells in the context of HIV-1 entry or infection. Indeed, the importance of cellular metabolism and infection

Fig. 2 *Mathematical theory of number and brightness.* Let us consider a system such that a monomeric protein (single circles) undergo the process of dimerization (paired circles). (a) Top row: before dimer formation, an average of six monomers are optically excited in the confocal volume. Bottom row: once dimers have been formed, an average of three dimers are optically excited in the confocal volume. Therefore, the concentration of fluorophores in the confocal volume is equivalent, such that the (b) intensity (I) means in both scenarios are the same. However, it is important to realise that after dimerization, the variance in intensity between the two rows are dissimilar, where the dimers (blue intensity trace, bottom row) possess a higher variance in intensity when compared to the monomers (black intensity trace, top row), due to the fact the fluorophores must enter and leave the confocal volume in pairs. This constant mean and difference in variance is depicted in (c) as intensity histograms (monomers in black, dimers in blue), such that the widening of the histogram shows the increase in variance in the dimer scenario. These intensity and variance values are utilised to calculate the number and brightness of entities in live cells for mobile particles.

has been shown in numerous publications. In particular, studies investigating the role of glycolysis and glucose uptake in HIV-1 infection illustrate that the host capacity for increased glucose transport could condition CD4⁺ T cell and macrophage susceptibility to HIV-1 infection. The possibility of label-free imaging of individual cell's metabolism within infected tissue would aid in understanding many questions related to HIV-1 pathogenesis. These types of quantitative measurements are further warranted because CD4⁺ T cells sitting in observation chambers most likely do not behave the same as CD4⁺ T cells residing in a 3D matrix. It is therefore very likely that their behavior will be very different also in tissue and organoids.

In addition to combining FLIM with multiphoton microscopy, on-line 3D single particle tracking originally developed by Hellriegel and Gratton has recently been multiplexed with two-photon microscopy, giving rise to: 3D Multi-resolution Microscopy (3D-MM). Currently, 3D-MM has been harnessed to investigate primarily coated nano-particles (100 nm) in limited cellular contexts, particularly endocytosis and transcytosis. Nevertheless, because these particles are of similar size to HIV-1 and other virions, and the imaging platform is equipped with a multiphoton laser, it is theoretically possible to image and track single HIV-1 particles in living tissue. However, the probability of detecting and tracking single HIV-1 labeled particles that would be subsequently infectious and productive in tissue is very low. This drawback necessitates automation of these experiments (both acquisition and analysis) to provide crucial information about the whereabouts and specific trajectories of infectious particles in physiologically relevant environments.

Encouragingly, a real-time 3D single-particle tracking approach using a dynamic moving laser spot, called 3D-DyPLOT, has been recently produced. Moreover, the authors were strikingly able to track VSV-G-eYFP pseudotyped lentiviral particles. The large observation area of this method (1 $\mu\text{m} \times 1 \mu\text{m} \times 4 \mu\text{m}$) and the improvement in detection sensitivity as compared to 3D-MM makes this technique a potential candidate to track fast single virions in tissue (Fig. 3). However, scattering, bleaching and limited photon counts coming from single virions could challenge long-term observations and these prospects need to be validated.

Although two-photon microscopy offers several advantages to elucidate previously unknown information about virus infection and metabolic pathogenesis in thick specimens (i.e., tissue and organoids), there are often several drawbacks. Firstly, the required ultrafast laser is prohibitively expensive, secondly the augmented photobleaching from the higher photon density relative to standard confocal microscopy precludes multiple excitation protocols. Additionally, naturally occurring chromophores often present in tissue samples must be considered when deciding if two-photon microscopy is the optimal method for an investigation.

Cryo Electron Tomography

Cryo-tomography (cryo-ET) is a 3D imaging technique that, when combined with advanced computational methods, aims to construct 3D images of cells and virus architectures in situ, as there is no requirement for fixation, dehydration or sectioning in sample preparation. Briefly, cryo-ET images are obtained from samples applied to glow-discharged grids with gold fiducial particles, which are subsequently vitrified by plunge-freezing. During imaging, after deciding on an optimal choice of electron dose and defocus (which generate contrast), a tilt-axis series of images are prepared and aligned to compute a tomogram of the desired area of interest, revealing its 3D structure.

Until recently, studies employing cryo-ET platforms were plagued by suboptimal labeling and low signal-to-noise ratios. However, the implementation of novel direct electron detectors, focused ion beam milling, phase plates and optimized subvolume averaging methods are expanding the capability of cryo-ET to investigate macromolecular complexes in the context of virus-host interactions. The first wave of these advances have been critical players in imaging viral glycoproteins of enveloped viruses. With these capabilities, cryo-ET has now been used to construct molecular models of viral glycoproteins and their interactions with receptors and antibodies, complementing investigations targeting novel pharmacological approaches or rational-vaccine design strategies against HIV-1.

The utilization of cryo-ET has been paramount in understanding the architecture of native HIV-1 Env in hopes of designing novel preventative strategies. In fact, cryo-ET was initially utilised to uncover the original 3D structure and numbers of HIV-1 Env trimer on the virion surface, ranging from 7 to 20 Env trimers across all isolates. Shortly thereafter, Liu and colleagues discovered the flexible mobility of the Env trimer upon binding of receptor CD4 and broadly neutralizing antibody b12 at a resolution close to 2 nm, paving the way for subsequent cryo-ET studies to uncover the multiple conformational changes HIV-1 Env must undergo to reach its prefusion conformation. These studies not only suggested strategies to generate antibodies against the trimeric nature of the Env spike, but also contextualized how some antibodies could stabilize closed pre-fusion conformations, explaining their broad and potent neutralization. These broadly neutralizing antibodies (bNAbs) generally target five sites against HIV-1 Env, and now the architecture of these bNAb-Env interactions have been determined through cryo-ET.

Although cryo-ET has been paramount in extracting structural information about HIV-1 glycoproteins interactions with receptors and neutralizing antibodies, much of this information is poorly resolved, and important parameters of neutralization (i.e., epitope exposure) must be inferred. Consequently, it is imperative for structural studies which utilize cryo-ET to be contextualized and/or complemented with other microscopy-based methods to confirm their results. For example early observations with cryo-ET illustrated HIV-1 Envs typically clustered on the envelope surface and this clustering of Env trimers correlated with infectivity. Furthermore, other observations of Env trimers showed their mobility on the virion surface upon approach to the host CD4⁺ T cells, forming a namesake "entry claw". Interestingly, subsequent studies have illustrated with STED microscopy that this entry claw is maturation dependent, a pioneering study unveiling the interdependence of the exterior virion surface Env mobility required for entry with the maturation-dependent Gag lattice rearrangement.

This utilization of both fluorescent imaging and cryo-ET has been a recurring motif in HIV-1 Env investigations and illustrates the importance of combining both approaches to answer questions regarding virus-host interactions to inform rational-vaccine

design. For example, single-molecule FRET (smFRET) may resolve individual macromolecular conformational rearrangements of viral glycoproteins, often revealing hidden conformational states undetected by alternative approaches due to their insufficient accumulation. Recently, the dynamic structural rearrangements of trimeric HIV-1 Env in native virions, visualised by smFRET, demonstrated how the Env trimer engaged with receptor CD4 and co-receptor CCR5 in different smFRET states whilst sampling different intrinsic structural configurations. These experiments showed that both unliganded laboratory-adapted and clinical isolate HIV-1 Env preferred the closed conformation (i.e., a low-FRET state), where the CD4 binding site was shielded by the V1/V2 loop at the trimer's apex, and that introduction of soluble CD4 domains or antibody fragments stabilized other smFRET states (i.e., high-FRET state) corresponding to open conformations depicted in cryo-ET studies. Furthermore, Markov modeling of the smFRET conformations revealed that the open conformation is achieved via a previously uncharacterized intermediate smFRET state, which has not been structurally characterized, yet may represent a critical motif for neutralization. Given that this intermediate state can be stabilized in some isolates by soluble CD4, it will be critical to characterise this state with the nanometer resolution provided by cryo-ET to uncover its significance. Finally, by utilising antibodies which bound the CD4-binding site, the

V1/V2 region, the V3 loop and fusion loop, it was shown that these antibodies stabilized the closed conformation previously suggested by cryo-ET-based investigations, demonstrating that a general mechanism of Env inhibition occurs by stabilizing the closed conformation (i.e., high-FRET state) such that the co-receptor binding site is obstructed.

Cryo-ET has provided structural breakthroughs to increase our understanding of the architecture of HIV-1 Env and has provided the preliminary structural knowledge to inspire further functional investigations to capture its dynamic nature and targets for neutralization. In addition to virus entry, cryo-ET has illuminated other important aspects of the virus lifecycle, such as virus maturation or integration, pinpointing the mechanism of novel maturation inhibitors (i.e., Bevirimat) and refining drug design of HIV-1 integrase inhibitors. Therefore, it can be expected that cryo-ET will continue to inform structural-based vaccine and therapeutic design as novel technologies increase its capability to image at near-atomic resolution.

Correlative Light and Cryo Tomography in Cells

Live, biological specimens are dynamic and pleomorphic, transforming the process of unequivocally identifying and localizing a molecule imaged in cryoEM into a difficult task. This is further complicated by the rarity and isolated nature of some biological events such as viral entry. However, this challenge of correlating structural and dynamic live-cell data can be resolved by the exquisite combination of the spatiotemporal information gained from fluorescence microscopy and structural data extracted from cryoET, and typically referred to as correlative light and electron microscopy (CLEM) (Fig. 4).

CLEM-approaches were first investigated by proof-of-principle experiments utilising HeLa cells to study the course of adenovirus infections and the subsequent changes to the nucleus during infection. Since then, a plethora of recent advances have propelled CLEM into a wealth of studies analyzing the virus-host interaction at multiple steps of the viral life-cycle. These advances include strategies to better manipulate and preserve viruses and cells in their near-native state, in addition to advanced labeling of macromolecular structures to localize tagged molecules both inside the cell and at its surface, a drastic improvement to canonical immunogold-labeling which limited labeling to cell surface and viral glycoproteins. Importantly, the development of the cryo-fluorescence light microscopy stage has made it possible to correlate the same vitrified, near-native fluorescently labeled sample at both the light and electron microscope. Because of these advances, in addition to both microscope software and hardware developments over the last decade the structural insights gained from cryoEM are merging with investigations in cellular physiology.

Advances in cryo-EM have been key to understanding various HIV-1-host interactions. For example, in a proof-of-principle experiment, a post-embedding CLEM approach was utilised to localize individual, non-fusogenic eGFP-MA labeled HIV-1 particles among filopodia-like protrusions of MDCK cell surfaces in electron tomograms. This study was expanded upon by Jun and colleagues, who combined high-speed confocal live-cell imaging and cryoET to create a novel platform which could locate ROIs for cryoET data collection for dynamic, diffraction-limited infectious virus particles, as well as characterise the spatiotemporal behavior of fusion-capable HIV-1 particles in living cells prior to and after membrane fusion. Specifically, samples which had been imaged live were imaged again by cryo-light microscopy after vitrification, enabling the HIV-1 particles to be relocated and visualised in 3D in situ, in addition to tracking the dynamics underpinning post-entry processes, such as HIV-1 capsid disassembly after membrane fusion. Because of these studies, it has been clearly demonstrated that CLEM is a feasible and robust method to analyze viral entry, and has been applied to other viruses recently such as vaccinia and herpes simplex viruses.

Perhaps one of the most profound examples of virus-host interactions can be surmised from virus restriction, and with a resurgence of interest in restriction factor biology, understanding the interactions between host and viral proteins can be

Fig. 3 Multiphoton microscopy and its capabilities to perform fluorescent lifetime imaging (FLIM) or online 3D single particle tracking (SPT).

(a) Comparison of conventional single photon confocal microscopy (left) with canonical two-photon microscopy. It should be noted that the focal point generated by the two photon beam generates considerably less light scattering and enables deeper penetration depth into the tissue specimen whilst creating a finer focal volume. (b) Model of a two-photon FLIM system capable of 3D SPT modeled after 3D-DyPlot. A pulsed titanium: sapphire laser without utilization of the 2D-EOD/Tag lens excites the sample for FLIM (explained further in c). For online 3D SPT, a 2D electric optical deflector deflects the laser beam to generate a 5×5 knight's tour pattern, achieving equivalent illumination over the $1 \mu\text{m} \times 1 \mu\text{m}$ square area. Simultaneously, to create a 3D dynamically moving laser point in the axial direction, the same beam is deflected by a TAG lens. Photons are collected by a detector (shown as HyD detectors), but can also be collected by avalanche photodiode and monitor cameras (i.e., sCMOS), where the real-time position of the particle is determined by the photon arrival times. This information is subsequently transferred to the 3D piezoelectric stage in order to keep the particle within the focal volume of the objective lens by counteracting its motion. (c) A general description of time-correlated single photon counting (TCSPC), where a pulsed femtosecond laser (i.e., Ti: Sa laser in b directed towards the dichroic) is used as the fluorophore's excitation source. Fluorophore excitation is followed by the emission of a photon with a given start-stop time. The excitation of the fluorophore can be depicted by the Perrin-Jablonski diagram and its various de-excitation paths after excitation. This excitation and fluorophore detection start-stop cycle is repeated many times, which leads to the construction of a TCSPC histogram relating the number of photon counts to the length of time needed to detect the fluorescence photon after laser pulse excitation (i.e., the lifetime of the fluorophore). Subsequently, the histogram is fitted with an exponential decay curve to extract the lifetime from the slope. (d) The 5×5 knight's tour pattern (left) generated by the 2D-EOD lens to ensure equal illumination across the specimen in the XY plane and its corresponding intensity image (right). These images are created over a long axial distance by the TAG lens without loss of fidelity via the deflection the 2D knight's tour above and below the center focal plane (far right), enabling approximation of the particle's axial position despite the fast tracking and low photon counts. (e) Final reconstruction of the TCSPC histogram (top) or the 3D trajectory of the tracked particle (e.g., labeled virus) in a tissue sample.

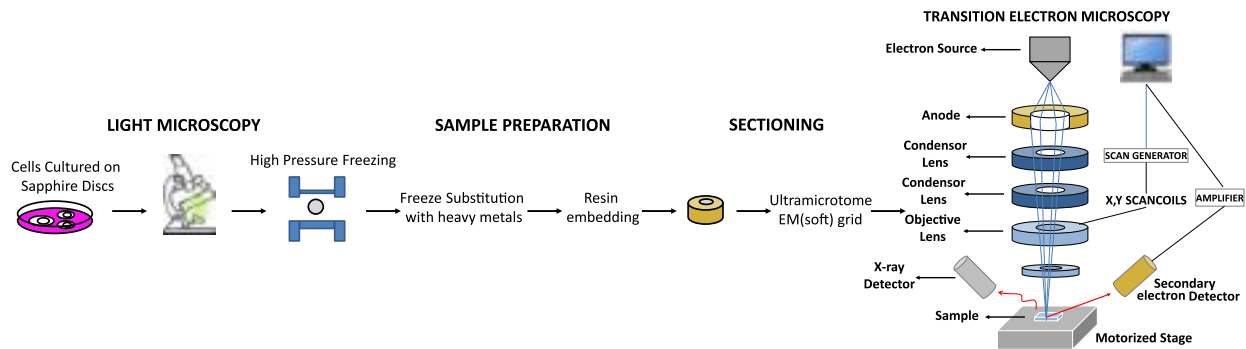

Fig. 4 Workflow of analysis of cells via CLEM scheme. Cells can be grown on sapphire disks and first analyzed under the light microscope. Cells labeled with fluorescent proteins or other means can help to localize proteins of interest and organelles but also quantitative imaging could be performed at this stage (this includes lifetime imaging, FLIM or super-resolution approaches that preserve the sample with mild illumination approaches). After this, cells are fixed and embedded in resin. The sapphire disks are then removed from the resin (polymerized) block. Trimming of the resin can then be performed and cells sectioned with a diamond knife. The very thin sections are then collected on slot grids and examined in a transmission electron microscope (TEM) to obtain ultrastructural information.

informed by their structure and activity in living cells. Recently, the arrangement of HIV-1 particles anchored to the host plasma membrane via tetherin, a restriction factor which abrogates virion release, has been uncovered via a CLEM-based approach. Before this study, investigations aiming to analyze the ultrastructure of HIV-1 tethered to human cells were limited to membrane-disrupting procedures such as heavy-metal staining and chemical fixation for TEM or SEM imaging. However, by imaging mCherry-Gag labeled HIV-1 VLPs tethered to HT1080 human cells via CLEM, it was shown for the first time at high-resolution in 3D that HIV-1 VLPs and virions were connected to the plasma membrane and each other by approximately 1–8 rod-like tethers over a range of distances between 7 and 37 nm which separated tethered HIV-1 virions from each other or from the plasma membrane.

Although CLEM has bridged high-resolution structural studies with the visualisation of dynamic biological events, several limitations of this approach to visualize virus-host interactions exist. For example, because the electron beam of many TEMs is unable to penetrate sample depths beyond approximately one micron, cryo-CLEM is limited to specimens with a thickness below ~ 750 nm, therefore excluding much of the cell's interior. However, this limitation is now being circumvented by multiplexing sectioning techniques with CLEM, such as cryo-ultramicrotomy, focused ion-beam machining to cut sections, and scanning TEM-tomography in order to visualize and preserve internal cellular structures and their fluorescent markers.

In addition to sample thickness, there remains a resolution gap between cryo-fluorescence microscopy and the sub-nanometer resolution obtained via cryoEM, which often impedes the interpretation of CLEM data. This is often due to the suboptimal optical properties of the resin of embedded samples, which influence fluorophore behavior via the cross-linking them and altering their environment, creating a challenge to introducing super-resolution to CLEM platforms. Furthermore, these single-molecule localization methods often rely on high excitation intensities on the sample to obtain optimum photon yields, which can cause sample devitrification and damage. Nevertheless, a general approach to cryo-super-resolution microscopy that enables subsequent cryoEM investigations has recently been envisaged utilising photoswitchable fluorescent proteins which remain active after vitrification, need not require cryoprotectants, and were utilised to image lipid nanotubes on intact mammalian cells for the first time at a localization precision of 30 nm. Undoubtedly, in combination with focused ion-beam milling to image intracellular structures, super-resolution CLEM will become a pioneering technique that will be widely available and applicable via the use of commercially-available tools and fluorescent proteins to localize region of interest (ROIs) with high precision.

Discussion and Outlook

Today, both electron and light microscopic imaging techniques are vital tools which can unveil the intricacies of different steps in viral replication cycles with unprecedented spatiotemporal resolution, particularly in the context of viral entry. In this article, we have highlighted seminal investigations which have illustrated the utility of an array of complex microscopy platforms while addressing their benefits, novelty and drawbacks for quantitative analysis of the processes under observation. Nevertheless, improvements continue to flood the literature, including the continual development of labeling strategies, semi-automated or automated data acquisitions as well as correlation methods and algorithms for processing SPT, FCS/FCCS and super-resolution imaging data are becoming increasingly unified and easily accessible for unfamiliar users. In this context, we firmly believe that novel insights revealing the mechanistic underpinnings of the entry and replication of many viruses will be ascertained. Undoubtedly, these observations will become invaluable for the development of novel and potent antivirals or vaccine strategies.

Atomic-Force Microscopy (AFM) Investigation of Viruses

Alexander McPherson, University of California, Irvine, CA, United States

© 2021 Elsevier Ltd. All rights reserved.

Atomic Force Microscopy Principles and Technology

A direct imaging technology that promises to have a significant impact on structural virology, and which is, in most ways, complementary to X-ray diffraction and electron microscopy is atomic force microscopy (AFM). The method has seen only limited use in the study of viruses, but its relatively low expense and simple principle makes it an attractive option. With AFM, the general, and sometimes specific features of a virus, even in impure preparations, may be swiftly determined. The images, which are three dimensional, not projections, are also rather easy to interpret, and much quantitative information may also be gleaned. The microscope itself is a small device, which has a size about that of a common household coffee pot, but may be accompanied by substantial ancillary computing support.

An AFM device and the principles by which it operates are shown schematically in Fig. 1(a). AFM instruments can be operated in either contact mode, or what is referred to as tapping mode. In contact mode, a probe made of silicon or silicon nitride is placed in near contact with the surface of interest, say the capsid of a virus, and then translated in a systematic raster mode over the surface. The AFM probe is a sharp stylus, like those pictured in Fig. 1(b), similar in function to a minute phonograph needle. The tip ideally has a single point, with a very small radius of curvature. The probe is mounted at the end of a short cantilever, typically 100–250 μm in length.

Fig. 1 Schematic drawing illustrating the principles of an atomic force microscope. (a) The vertical deflection that the cantilever tip experiences upon encountering some topological feature on a specimen is amplified through a reflected laser beam, which is tracked and reported by a split-diode photoelectric detector. Scanning takes place in a fluid-filled (or dry if preferred) cell of about 75 μL in volume. The sample is translated in a raster manner by piezoelectric positioners upon which the fluid cell is mounted. (b) Scanning electron micrographs of high-quality AFM tips etched from silicon.

Scanning is achieved by translating the sample beneath the probe, using a piezoelectric positioned x–y stage, along a continuous sequence of raster lines. As the probe tip passes over the surface, it interacts through “aggregate atomic forces”, which remain somewhat mysterious, with structural features on the surface. Encounters with these substructures cause the probe to be displaced vertically as the tip rides across. Exceedingly small displacements of the tip are amplified by deflection of a laser beam that is reflected from the upper surface of the cantilever, and these deflections are detected and tracked by a split photodiode. Photoelectric circuitry converts the deflections into height information. The resulting scan data, recorded as a digital topographical image, can then be presented in a number of visual formats.

In contact mode of operation, the data may be acquired as either “height” or “deflection” information, or the data from both modes may be obtained simultaneously. In “height” mode the sample surface is maintained at a constant distance from the probe tip by the piezoelectric positioner below, through a feedback mechanism. The cantilever deflection in this case is very small. In “deflection” mode the sample is stationary and actual cantilever deflection data are collected. Microfabricated cantilevers exert a force on the substrate surface of about 10^{-9} to 10^{-12} N/m, and, as one might anticipate, the resolution of the technique depends on the degree of force employed. Up to a point, the greater the force between probe and surface, the more sensitive the probe is to surface variations. On the other hand, the greater the force, the more the probe may perturb the surface.

Sample perturbation and other problems arising from unfavorable probe – surface interactions have been obviated to a great extent by the development of “tapping” mode instruments. With tapping mode, the probe tip is not in continuous contact with the sample surface, but rapidly oscillates up and down as it is scanned over the surface, essentially “tapping” its way and gently sensing the heights of obstacles it encounters. In tapping mode, the vertical position of the sample is continually adjusted by a feedback mechanism to maintain the amplitude of the freely oscillating probe constant. Image acquisition time ranges from 0.5 to 4 min, with shorter scan times usually associated with greater tip – specimen interaction. Tapping mode minimizes contact between the probe tip and the sample surface and greatly reduces lateral forces.

The “tapping mode” approach has proven a significant boon in biological investigations as it has allowed the characterization of samples that would otherwise be too soft or too fragile to withstand contact mode examination. Operating with tapping mode in a liquid environment presents some complications due to fluid dynamics, but these are not severe. A constraint that sometimes presents obstacles during analysis in a liquid medium is that the specimen under study must be fixed to, or made to adhere firmly to the substrate surface of the fluid cell, which may be glass, cleaved mica, plastic, or any other hard material. To achieve this, it may be necessary to treat the substrate with various reagents, such as poly-L-lysine, to induce better adhesion of samples. If this condition is not met then the specimen will move due to interaction with the probe and no useful information is gathered.

One particular feature of AFM must be borne in mind whenever one is interpreting images. The one or two-dimensional trace obtained of any object, or surface substructure, is the convolution of the tip shape with that of the feature being scanned. This is illustrated in Fig. 2. An image of an object scanned with a broad, dull tip is not the same as that acquired with a sharper tip. In particular, while the height of the object will be the same regardless of the tip shape (because the maximum vertical deflection of the cantilever tip would be the same), the lateral dimensions will not. The broader tip yields a broader object, the sharper tip produces the more accurate size. Because one does not, in general, know the tip shape one is working with at the time, the image cannot be easily deconvoluted to provide the true dimensions. Hence, height information is almost always trustworthy, but lateral measurements are suspect. The reliability of lateral measurements can, however, be increased if some standard having defined spatial features is first scanned and its known spacings or cell dimensions compared with those in the image. Such standards may be etched grids on silicon, or the surfaces of protein crystals.

The areas of scanning fields may range from 20 nm^2 to $150 \mu\text{m}^2$, with a spatial resolution on biological samples approaching 1 nm in the best of cases. Thus it provides precise visual detail over a size range that eludes most other techniques. Lateral resolution varies depending on the prominence of features and the deformability of the specimen. For small isolated samples on mica, such as macromolecular assemblies and single virus particles, the resolution is most limited by the size and structure of the tip. Commercially available tips have radii of curvature in the 5–20 nm range and provide resolution at fractions of those dimensions.

AFM of Biological Specimens

On large soft samples, such as living animal cells lateral resolution may be more limited by the motion and deformation of the cell surface in response to tip pressure than by tip structure. Height resolution for all samples is typically better than 1 nm. Because visualization can be carried out in a fluid environment, specimens may suffer no dehydration as is generally the case with electron microscopy, and they usually require no fixing or staining. Indeed, specimens can be observed over long periods, so long as they stay relatively unchanged and immobilized during a single frame interval. For the most part, even living cells seem oblivious to the presence of the probe tip.

Specimens, however, are not always best visualized under physiological conditions, particularly when high resolution is desired. Because cantilever tip pressure, even in “tapping mode”, may produce deformation, for example of a cell membrane, in some cases fixation is the better option. This, as with light microscopy histological procedures, usually relies on glutaraldehyde, paraformaldehyde, or osmium tetroxide fixation, followed by dehydration and imaging in water-alcohol mixtures, or in air. These methods have been developed by microscopists for more than a century to preserve the natural morphology of a sample but still allow high-resolution imaging. While not as ideal as *in situ* observation (the cells of course are no longer alive or viruses infective), fine details of their structures can be visualized that would otherwise be obscured by membrane flexion.

Fig. 2 Schematic illustration of the convolution of the shape of the AFM tip with the shape of the feature or particle being scanned. The side of the cantilever tip contacts the object and begins to produce a deflection of the cantilever before the tip apex actually reaches the object. Similarly, the opposite side of the tip is still in contact with the object even after the apex itself has passed. Thus, the total deflection implies a virtual lateral dimension for the object that is greater than its actual dimension. The difference between the virtual and actual dimensions is a function of the width of the cantilever tip. The sharper the tip, the more accurate the observed dimensions and the greater the resolution attainable.

Although AFM was initially employed to study the crystals and the crystallization of small icosahedral plant viruses, atomic force microscopy (AFM) does not require that the virus be crystallized or otherwise ordered. It is applied to individual particles and does not yield an average structure over an entire population. It does not require that the virus have a symmetrical or uniform architecture, or even that all particles be the same in structure. Thus, it is equally applicable to small icosahedral viruses such as Brome Mosaic Virus and satellite tobacco mosaic virus, to helical viruses such as Tobacco Mosaic Virus, to completely irregular, complex viruses like Vaccinia, or the retroviruses. There is no size restriction. It has been used to analyze small plant viruses to massive icosahedral viruses such as PBCV-1, an algal virus and mimi virus, one of the largest viruses known.

Initial Observations From AFM

A valuable qualitative result that emerges almost immediately from AFM images is what the virus looks like, what is its overall architecture, and how similar are particles to one another. Are they uniformly the same in appearance, or are there a variety of forms? Even a cursory AFM investigation may quickly reveal certain general features that allow rapid classification, as illustrated by the various structural classes of viruses shown in Fig. 3. The virions may be spherical, cylindrical, or filamentous. They may have symmetrically arranged capsomeres or other surface units, fibers, protruding vertices, prolate or icosahedral shapes, unusual morphologies, pleiomorphic character, etc. Tail assemblies may be observed directly, as on phages for example. AFM is, therefore, a useful tool for simply deducing the kind of virus one is dealing with, whether more than one kind of virus is present in a population, and the general level of contamination that may accompany the virus; cellular material, degraded virions, and macromolecular impurities of all sorts.

A fundamental parameter for virus particles is their diameter if they are spherical viruses, or their diameter and length if they are helical. AFM can provide measures of these in both the hydrated and dried state, which also gives an estimate of the degree of shrinkage they undergo as a result of dehydration. Because of the finite tip size, and tip-to-tip variation in radius of curvature, it is

Fig. 3 *Virus shapes and forms.* (a) Crystal of satellite tobacco mosaic virus, a $T = 1$ icosahedral plant virus. (b) Rod shaped tobacco mosaic virus having a helical architecture. (c) Ty3 retrotransposons, a proto-retrovirus of icosahedral design. (d) Filamentous bacteriophage that infect bacteria in the Pacific Ocean. (e) A single virion of the membrane encapsidated, RNA containing SARS virus responsible for severe human respiratory disease. (f) Three virions of vaccinia virus with their prominent "lateral bodies" and coatings of hair-like fibers. (g) Tipula Iridescence Virus, a large membrane encapsidated, icosahedral virus that infects insects. (h) A single virion of HIV that produces AIDS in humans exhibiting a surface of Gp120 protein puffs. (i) Virions of Moloney-Mouse Leukemic virus. (j) Virions, nearly 800 nm in diameter, of the largest virus known, mimi virus. The virus is immediately recognizable by the remarkable star shaped structures it displays at one vertex of its icosahedral capsid. (k) PBCV-1 algal virus, a large virus of icosahedral design. (l) Tailed cyanophage that infect photosynthetic bacteria in both fresh and salt water bodies. Here they are seen clustered about and infecting a single bacterial cell.

risky to measure linear dimensions directly by AFM as was discussed above. It is, however, safe to measure the heights of objects above the substrate plane, and the distances between the points of maximum elevation (e.g., capsomere to capsomere) on particles, or center-to-center distances (e.g., particles in a crystal or in a cluster). This last approach can be applied to noncrystalline or paracrystalline arrays of viruses, both helical, rod shaped, and spherical viruses.

For spherical and cylindrically symmetric particles, measurements of particle heights above the substrate plane yield reasonably accurate values for their diameters and individual measurements are usually accompanied by rather modest error, generally of the order of 5% or less. By repeating measurements for a number of particles in the field, and using different scan directions, good statistics can be obtained, and histograms of size distributions compiled. Precision of a few angstroms is possible. Histograms of particle sizes are often informative. If the distribution is a simple Gaussian, then it can be presumed that particles of only one general morphology, or icosahedra of only one triangulation number are present, but that their diameters vary to some degree about the mean, perhaps due to physiological state or degree of maturation. If, on the other hand, a more complex distribution is observed, one having multiple peaks and shoulders, then particles of separate classes may be present. From such a histogram analysis it was deduced, for example, that Ty3 retrotransposon particles existed as icosahedra having triangulation numbers 3, 4, and 7.

As shown by **Fig. 3**, the surfaces of virus particles vary topologically as a function of their composition and architectures. Plant viruses, for example, generally exhibit protein capsids with few embellishments, and this is true of many simple animal viruses, such as poliovirus, and filamentous, rod shaped, and non-tailed bacteriophages as well. These geometrical capsids are generally based on icosahedral or helical architectures, and clusters of coat protein subunits, or capsomeres, are symmetrically distributed. Complex animal viruses on the other hand, though they may contain an icosahedral capsid in their interior, often have either a lipid

(b) A single virion, about 30 nm across of the icosahedral plant virus Turnip Yellow Mosaic Virus displaying a $T = 3$ arrangement of hexameric and pentameric capsomeres. (c) Hexameric capsomeres are separated from one another by trimeric proteins on the surface of the icosahedral capsid of a cyanophage. (d) The icosahedral virion of a Ty3 retrotransposon, a proto-retrovirus. (e) The icosahedral DNA filled head of a T4 bacteriophage. (f) Trimeric protein capsomeres composing the large faces of the icosahedral PBCV-1 algal virus.

membrane over their surface, a covering of protein clusters, or even a fur like coating of fibers. These characteristic surfaces are usually apparent by AFM. With the aid of some histological procedures, such as osmium tetroxide fixation, or protease treatment, can be identified and delineated with a high degree of precision. Some examples of icosahedral capsids and cores are presented in Fig. 4.

Icosahedral capsids, or bullet shaped or elongated capsids based on that symmetry, can be characterized in terms of the structure of the fundamental capsomere, along with the icosahedral triangulation number, T . In many cases the exterior shell of a virus may not be icosahedral, but it might possess an inner capsid that is. For example, though membrane covered and of pleiomorphic external shape, herpes simplex possesses a nucleic acid containing capsid of icosahedral form $T = 16$. Mimivirus exhibits a complex outer surface coated with a forest of fibers, but it too contains an icosahedral core with a triangulation number lying between $T = 324$ and 381 . The T number, then, contains half of the information one needs to describe an icosahedral capsid.

Triangulation Numbers of Icosahedra

The triangulation numbers of icosahedral viruses can often be deduced from AFM images like those in Fig. 4. In the case of Ty3 retrotransposons, a proto retrovirus, it was found that virions existed in three different diameters, and three different architectures corresponding to T numbers 7 (the largest fraction of the population), 4, and 3. AFM images of the surface capsomere distribution could be triangulated visually, as in Fig. 5, by defining the arrangement of hexamers with respect to pentamers. The T number was thereby defined. Of particular interest were the $T = 7$ particles which could conceivably exist in either of two enantiomorphs, d and l . Because height information is preserved in AFM images, so is handedness. Thus it was possible in the case of the $T = 7$ Ty3 virions to determine that their actual T number was $7d$.

A somewhat different approach must be taken with very large icosahedral capsids, like some of those in Fig. 4, which include PBCV-1 and mimivirus. For these viruses it is necessary to determine two indices h and k , which define T ($T = h^2 + hk + k^2$), by following a row of hexagonal capsomeres from one pentagonal vertex to the next icosahedral edge, and counting the number of capsomeres along one edge h and the other k (the h and k coordinates of the intersection point on the icosahedral edge). This approach was used to determine the T numbers of the iridovirus PBCV-1 and the capsid architecture of mimivirus. While the

Fig. 5 The icosahedral symmetry of the Ty3 retrotransposon, a protoretrovirus that infects yeast, was established by AFM. It was further shown that Ty3 existed in three different icosahedral forms corresponding to T numbers of 3, 4, and 7. (A) The left panel shows a Ty3 particle, and the right panel shows the same particle with a T7 icosahedral net overlay. Pentagonal vertices are in red. The center diagram is that of a triangular face of an icosahedron showing positions of pentagonal and hexagonal capsomeres for T7. (B) Another, smaller particle of Ty3 and the equivalent overlay and diagram showing it to have T4 icosahedral symmetry.

T number describes the overall distribution of capsomeres on the surface of an icosahedral capsid the distribution of subunits within capsomeres can also sometimes be deduced by AFM analysis.

Analyses like this were used in the case of the large algal virus PBCV-1, shown in **Figs. 3(k)** and **4(f)**. Knowing the diameters of capsomeres is often of considerable importance, even when individual subunits cannot be resolved. In mimivirus, seen in **Figs. 3(j)** and **4(a)**, for example, capsomere diameter provided a crucial clue in delineating the capsid architecture, and permitting subsequent detailed analysis and reconstruction by cryo-EM. Although capsids of native HIV have yet to be visualized by AFM, helical tubes of capsid protein reassembled *in vitro* have, and one is shown in **Fig. 6(a)** along with examples of other reassembled virus particles (VLPs). In these tubes a hexagonal arrangement of coat proteins could be clearly seen, and this provided support for a capsid model based on modified icosahedral architecture.

Recombinant and Mutant Virus Particles

Not only native viruses, but also recombinant and mutant particles can, and are frequently recorded in AFM investigations. **Fig. 6** presents an array of examples. In **Fig. 6(a)** is seen a helical tube that is occasionally generated when the recombinant capsid protein of HIV is made and allowed to assemble in bacterial cells. In **Fig. 6(b)** are particles of recombinant Gag protein from Ty3 retrotransposons produced and assembled in *E. coli* that fail to assemble into icosahedral shells, and similar results with Mason-Pfizer Monkey Virus. **Fig. 6(c)** is a structure, rather common in preparations of T4 bacteriophage, a twin tailed virion next to a normal, single tailed virus. In **Fig. 6(d)** a lymphocyte infected with a mutant of Murine Leukemia Virus (MuLV) that lacks the ability to separate itself from the host cell membrane. It forms, instead, the extended comet-like protrusions that decorate the host cell surface. **Fig. 6(e)** is another mutant of MuLV that fails to make its normal (Gp120) surface protein, giving rise to what are termed “bald” particles. In **Fig. 6(f)** is a crystal of Brome Mosaic Virus, a small (28 nm, T = 3) icosahedral plant virus. What is striking is the inclusion in the crystal of a mutant of smaller diameter (likely a T = 1 particle), and a mutant of larger diameter (likely a T = 7 particle), illustrating the somewhat promiscuous nature of icosahedral shell assembly.

The helical tubes reassembled from HIV Gag protein in **Fig. 6(a)** reminds us that, although we have emphasized spherical particles to this point, helical and rod shaped structures having periodic sub structure are also excellent specimens for AFM analysis. These frequently appear in investigations of intact viruses, and even in studies of spherical viruses when their interiors are explored. While we tend to think of virus particles as geometric solids such as icosahedrons, or layered structures such as mimi, herpes, or vaccinia, they often include or produce substructures that represent completely different material forms. Among these are fibers of various sorts, and membranes.

Fig. 6 *Mutants and recombinant particles.* (a) Helical tubes, a product of in vitro self-assembly of the Gag protein of human immunodeficiency virus. (b) Particles reassembled in vitro from a truncated form of the Gag protein from Mason-Pfizer monkey virus. (c) Preparations of T4 bacteriophage were found to commonly contain mutant virions like the double tailed example seen here next to a normal virion. (d) AFM image of 3T3 cells in culture that are infected with a mutant form (gPr80^{gag}) of Moloney murine leukemia virus. The virus, upon budding, is unable to separate completely from the host cell membrane and forms long, comet-like extensions from the cell surface. (e) A mutant of Moloney murine leukemia virus that, genetically, lacks the capacity to make envelope protein. As a consequence, it appears as a “bald” virus that exposes its limiting lipid membrane to the exterior. The undulations and variations of the membrane surface are an effect produced by local movement of the membrane in response to AFM tip pressure. (f) A crystal of brome mosaic virus. Though most of the crystal is composed of conformist T3 particles with the standard diameter of 30 nm. The crystal also contains an exceptionally small virion, probably a T = 1 icosahedra lacking RNA, and one exceptionally large virion, probably T4 or 7, likely containing multiple copies of RNA.

Virus Fibers and Membranes

In **Fig. 7** are examples of fibers, all of viral origin. They include the six tail fibers of a bacteriophage emerging from its hexagonal base plate, fibers that first engage the host cell surface, **Fig. 7(b)** are the surface fibers of mimi virus, and **Fig. 7(c)** those of vaccinia, a coating that gives the intact viruses the appearance of fur covered particles in AFM images. In **Fig. 7(d)** are fibers of unknown function that are prolific in AFM images of disrupted mimi virus. They resemble collagen fibers, but exhibit a different helical periodicity of 7 nm. The 3 + 1 decorated fibers of some cyanophages in **Fig. 7(e)**, though prominent, remain of mysterious but intriguing function that may select “life at sea” and the search for hosts in a dispersed environment. **Fig. 7(f)** contains the DNA strands from a T4 bacteriophage.

Fig. 8 presents three examples of viral membranes encountered in AFM investigations of viruses. In **Fig. 8(a)** the icosahedral core of a mimi virus is encapsidated by a thin, presumably lipid membrane surrounding it like a corona. In **Fig. 8(b)** the membrane sheet of a herpes virus has been partially pulled away to reveal the underlying T=25 icosahedral core. In **Fig. 8(c)**, following expulsion of cores, the membrane coverings of vaccinia, heavily studded with protein aggregates, litter the AFM substrate.

With AFM, it is not essential that highly purified virus particles be used as samples, although that might be ideal. Moloney Mouse Leukemia Virus particles are accompanied by a background of protein molecules in **Fig. 3(i)**, for example, but they are nonetheless distinct in their features. The same was true of the TMV in **Fig. 3(b)** and the phage particles in **Fig. 3(l)**. Because individual particles can be investigated whenever a good specimen is spatially distinct from the surrounding rubble of proteins,

Fig. 7 *Viral fibers.* (a) A view along the axis of a bottom segment of a cyanophage tail assembly that is standing upright on the AFM substrate. The tail fibers are played out, showing their segmented character. (b) The surfaces of mimi virus are coated with fibers of uniform length having a distinctive head like those shown here. (c) Vaccinia virus is coated with the short, thick fibers seen here, discarded from the virions as they decompose. The fibers give the vaccinia the appearance of being coated with fur. (d) AFM images of unique fibers, having a pronounced 7-nm repeat along their lengths, that were observed in abundance when mimivirus capsids were disrupted. (e) A class of cyanophage has two fibers originating at the collar between the icosahedral head and the helical tail. The fibers are always decorated by the 3 + 1 arrangement of distinctive, attached protein masses near their distal termini. (f) The bright mass near the center of the image is a cyanophage head that has burst. The strands of DNA are seen emerging from the head and spreading on the substrate.

Fig. 8 *Viral membranes.* (a) A mimi virus, with its fivefold aperture in the process of opening to release its sac of DNA, is seen enclosed in a thin membrane envelope. (b) The white sheet of the membrane coating a herpes simplex virus has "splashed" to one side of the capsid and lies on the substrate plane. (c) Vaccinia virus cores are encapsidated within membrane envelopes, which are heavily decorated with proteins and their aggregates. Upon expulsion of the cores the empty envelopes remain and are seen here.

cellular debris, and biological detritus, it may still yield excellent images. A problem, however, is that biological debris often adhere to, and foul the AFM tip, and this severely degrades the quality of images.

Infection and Budding From Host Cells

Viruses on the surfaces of host cells, or within the cytoplasm, can be visualized as well as free particles, and sometimes with superior acuity, because they are better immobilized. They may be seen entering cells upon infection, or budding from cells after replication and assembly. This often provides valuable insights into which cells in a population are producing virus, the distribution of virus particles on the surface of the cells (e.g., are there preferred sites for budding?), and some details of the budding process itself.

In **Fig. 9(a)** and **(d)**, for example, human lymphocytes in culture are seen virtually coated with HIV budding from their plasma membranes. Investigation of a large population of cells, however, showed that this was an unusual occurrence, in that most cells exhibited only a dozen or less HIV on their surfaces. Thus only a few cells seemed to account for the great majority of virus. Algal cells have both a cell membrane and a cell wall that must be breached in order for cyanophage to enter. In **Fig. 9(b)** an algal cell is under attack from a host of cyanophage. **Fig. 9(c)** is an AFM image of a disrupted amoeba cell infected with mimivirus, its nucleus in the lower left. The cell contains on the order of a thousand new particles.

Specific and Special Structural Features

Special features abound when more complex viruses are imaged by AFM, and these often, but not always, are found at specific, specialized vertices of icosahedral viruses, or their cores. In **Fig. 10(a)** is shown the pentagonal star at a unique fivefold vertex of a PBCV-1 algal virus and in **Fig. 10(b)**, the far more complicated star shaped structure that fastens shut the internal cavity of mimivirus that contains its DNA. In this case the function of the star has been deduced primarily through AFM investigation and

Fig. 9 Virus infected cells. (a) and (d) are human lymphocytes grown in culture that are infected with HIV. The budding virus appears to literally coat the surfaces of these super-infected cells. (b) The icosahedral heads of cyanophage are seen at the surface of an infected bacterium, their tails engaged with the cell surface. (c) An amoeba cell infected with mimi virus has been disrupted allowing the AFM to record the contents. The nucleus of the cell can be seen occupying the lower left. The cell is filled with new virus particles emerging from the several “virus factories” in the cytoplasm.

Fig. 10 *Special features of complex viruses.* (a) A specialized cluster of five proteins, with another protein at the center, that occupy the 12 unique vertices on the surface of PBCV-1. All of the proteins in these clusters are clearly different in structure from the normal capsid protein (b) Image of the “stargate,” five-vane apparatus found at only a single pentameric vertex of mimivirus. The apparatus provides a mechanism for the release of the encapsidated DNA. (c) Helical tail assembly from bacteriophage T4 that is responsible for injection of the phage DNA into its host. (d) Air-dried vaccinia virus. Retraction of the membrane and overall shrinkage emphasize the lateral body at center. A unique feature of vaccinia virus is the presence of two such lateral bodies associated with each virion. (e) A cyanophage displays two unique fibers decorated in a $3 + 1$ fashion with large protein aggregates. The fibers always have the same lengths, four aggregates, and consistent intervals between the aggregates. (f) AFM image of adenovirus. A noteworthy feature of adenovirus is that degradation of the virions invariably initiates and proceeds with loss of pentons at the 5-fold vertices, leaving particles perforated in an icosahedrally symmetric manner.

shown to be the gateway for delivery of the nucleic acid. The helical tail of prominent pitch, a tube essential for injection of nucleic acid and that is joined to a singular five fold vertex on the head of a $T = 7$ icosahedral head of a bacteriophage is shown in [Fig. 10\(c\)](#). In [Fig. 10\(d\)](#) is an example of the prominent, embedded “lateral body” of a vaccinia virus, and in [Fig. 10\(e\)](#) the curious $3 + 1$ decorated fibers attached to the head of a cyanophage. In [Fig. 12\(f\)](#) a surface fiber important in host recognition, has been pulled from a fivefold vertex of an adenovirus.

Dissection of Complex Viruses

One might think that because AFM provides images of the surfaces of objects, and does not peer into their interiors, as do X-ray diffraction and electron microscopy, that they would be of little value in delineating the interior structure of viruses, the layers beneath the external surface. This is not true, however, as we can apply the same technique that has been used by anatomists for centuries, dissection. With the aid of chemical, enzymatic, and physical tools, we can systematically pare a complex entity, including a virus, down to its core, layer by layer. At each stage, AFM may then be used to visualize what remains, and what has been removed as well.

This approach is particularly effective with large, complex viruses such as Vaccinia Virus, as illustrated by [Fig. 11](#), or Mimivirus. With these large assemblies, ordered and disordered protein shells, lipid membranes, and the nucleic acid within can be revealed and analyzed. By deconstruction, the architecture of particles is revealed, and, at the same time, the kind of biochemical interaction that maintains each level of structure is delineated as well.

Among the most useful agents for chemical dissection have been detergents, usually 0.5%–2% of some non-ionic detergent such as NP40, and reducing agents such as DTT or DTE. The former causes protein structure to gradually unravel, and detergents strip away lipid membrane. The latter reduce disulfide bonds and liberate polypeptides otherwise bonded to one another.

Fig. 11 Four stages in the chemical and enzymatic dissection of vaccinia virus. (a) An intact vaccinia virus virion. (b) The core of the virus obtained by treatment with a nonionic detergent (NP-40) and dithiothreitol, a reducing agent. (c) The ghosts, or capsules, that remain after the cores have been treated with proteases, which also produces release of the viral nucleic acid. (d) Masses of DNA released onto the AFM substrate by disrupted viral cores. The arrow indicates a disrupted vaccinia virus core adjacent to the DNA.

Fig. 12 Damaged retroviral virions. Retroviruses are fragile and often are disrupted or damaged by the shear forces of preparative centrifugation alone. These damaged particles frequently expose, for AFM visualization, internal structure and reveal unique elements of the virus architecture. (a) A virion of Moloney murine leukemia virus where the outer shell of envelope protein, lipid membrane, and matrix protein have been partly torn away to reveal, like the kernel of a nut or the pit of a fruit, the nucleic acid-containing capsid that it enshrouds. From such images we can obtain quantitative measures of the thickness of the virus shells and the diameters and structural character of the capsid within. (b) A human immunodeficiency virus that has been shorn during centrifugation and has completely lost the protein capsid that it contained.

Disulfide bond reduction appears to be particularly important in large, complex viruses where such covalent linkages cross-link coat proteins and stabilize capsids.

In some cases, non-ionic detergents are insufficient to disrupt structure and more vigorous ionic detergents such as SDS must be used. There is difficulty with SDS, however. It tends to have an all or none effect, so that upon reaching a concentration sufficient to disrupt viruses, it completely degrades them uncontrollably. SDS can also produce artifacts due to drying on the substrate.

The most effective enzymatic tools have been proteases that degrade polypeptides. These are particularly useful because they have a range of activities and a spectrum of specificities. As a consequence, a whole variety of proteases have been employed, and these include trypsin, bromelain, proteinase K, subtilisin, and mixtures of pancreatic proteases. Viruses are usually exposed to the proteases for anywhere from 15 min to several hours, or even overnight, at concentrations 0.5 mg/ml to as high as 5 mg/ml. The proteases must be washed from the virions with buffer or water before imaging as they otherwise produce a dense, irregular background that makes imaging problematic, and they foul the cantilever tip.

Physical forces have also been used to disrupt viruses, and often fortuitous perturbations, resulting simply from preparation and handling, have proven structurally illuminating. Heat, for example, was used to open TYMV to release its encapsidated RNA, and direct physical pressure on mimivirus sandwiched between two layers of atomically smooth, cleaved mica, as well. There are also instances where “hammering” of individual particles with the AFM tip has been utilized, taking advantage of the fact that AFM can serve as a tool as well as an imaging device.

It is occasionally unnecessary to actually treat viruses with any chemical or biochemical agent to see inside, as the physical stress of preparation and purification may result in damaged or partially degraded particles. These may expose interior structural features otherwise not apparent. Retroviruses, in particular, are physically fragile. Some MuLV, as shown in Fig. 12, when subjected to the shear forces of centrifugation, lose portions of the shell surrounding the capsid. This permits direct visualization of the virus core still embedded within the layers of envelope and matrix protein.

HIV is another example where even the mildest procedures produce some damaged virions. Although the cores of HIV have not yet been visualized by AFM, likely due to their fragility, the remainder of the virus, those without the cores have. Such partially disrobed particles, both MuLV and HIV, provide specimens that can be subjected to quantitative examination and thereby yield the dimensions, the thicknesses of internal layers of structure, and they give some clues as to their components as well.

Fig. 13 *Nucleic acid.* (a) Strands of DNA spreading on the AFM substrate from a broken icosahedral head of a cyanophage. (b) Masses of DNA released by vaccinia cores upon their decomposition. (c) RNA lost from chemically degraded satellite tobacco mosaic virus. (d) DNA emerging from burst heads of T4 bacteriophage. (e) RNA heavily complexed with proteins is seen to form the “pinwheel” structures shortly after decomposition of the restraining shells of the SARS virus. (f) A mass of DNA studded with proteins pours from a single mimi virus after it disgorges its sac of the nucleic acid.

The best example of a complete dissection of a complex virus using AFM is that of Vaccinia virus, a pox virus of about 300 nm diameter that is delimited by a lipid membrane. It contains a double stranded DNA genome bounded by several protein shells. It also has associated with its inner core two unusual protein assemblies of still unknown function, known as lateral bodies.

As illustrated in Fig. 11, vaccinia could be sequentially degraded with 0.5% NP40 non-ionic detergent combined with 0.05 M DTT, followed by exposure to this same mixture but containing either trypsin or proteinase K, or to the proteases alone. Four stages in this process were presented in Fig. 11. In the end, the innermost core was breached and the DNA was exposed. From images of the DNA emerging from the core, it was deduced that while some portion of the encapsidated DNA was heavily integrated with protein, the vast majority was largely naked, with only occasional associations with protein.

Visualization of Viral Nucleic Acid

The nucleic acids of viruses, from a structural standpoint, are of considerable interest, and in particular, how they are condensed and packaged inside capsids and cores. Clearly, packaging is accomplished in different ways by specific families of viruses. It is unlikely, for example, that bacteriophage and pox virus package their genomic double stranded DNA the same way. The packing densities of the nucleic acid differ by more than tenfold. Nor is it likely that large, single stranded RNA containing viruses, such as retroviruses, package their genomes the same way as do $T = 1$ or $T = 3$ icosahedral viruses. Certainly, helical and filamentous viruses use entirely different mechanisms.

AFM investigations have been conducted on RNA extracted by phenol from a series of small icosahedral viruses, and from Tobacco Mosaic Virus, the classical rod shaped, helical virus. The spherical viruses included poliovirus, Satellite Tobacco Mosaic Virus, Turnip Yellow Mosaic Virus, and Brome Mosaic Virus. In these studies, the gradual unraveling of the tertiary structure of the RNA, and ultimately the secondary structure as well, could be produced in stages simply by heating. A counter example was provided by Tobacco Mosaic Virus RNA, which appeared initially as a thread, a completely extended molecule lacking any

Fig. 14 *Delivery of viral nucleic acid.* (a) and (b) show cyanophage before (a) and after delivery through the tail injection mechanism. The tail is fully extended in (a) and compressed in (b). After ejection, the particle in (b) is surrounded by stands of DNA on the AFM substrate. (c) A remarkable image of a mimi virus icosahedral core disgorging its sac of DNA through the open "stargate". (d) The core of a vaccinia virus is seen in a state of decomposition which allows subsequent release of massive quantities of, initially, highly self entwined, cables of DNA. (e) Distinctive rings of RNA complexed with proteins that form as the SARS virus releases its genome. (f) Simultaneous emission of RNA from satellite tobacco mosaic virus upon gentle treatment with phenol.

secondary structure. With time, it began forming local secondary structural elements and eventually condensed into forms similar to those seen for the RNA from the icosahedral viruses. The upshot of the study was that the single strands of RNA spontaneously condensed as linear arrangements of stem – loop substructures following synthesis, that the condensed RNA bound coat protein to it, and the two cooperatively coalesced into the completed particle. In those studies, AFM proved itself an able technique for directly visualizing nucleic acid structure, demonstrating its fluidity, and suggesting the mechanisms by which it is encapsidated.

DNA and RNA have quite different appearances in AFM images, and this is evident in **Fig. 13**, which presents both kinds of nucleic acid. In **Fig. 13(a)** and **(d)** are seen the genomes of T4 and cyanophage, respectively, emerging from viral phage heads. In **Fig. 13(b)** are enormous masses of DNA released from the cores of only a few vaccinia virus. In **Fig. 13(f)** DNA pours forth from a single mimi virion, the nucleic acid highly complexed with proteins. In **Fig. 13(c)** RNA from disrupted satellite tobacco mosaic virus (1058 nucleotides) are displayed on the AFM substrate. In **Fig. 13(e)** The RNA genome of a SARS virus, heavily associated with protein, forms a characteristic pinwheel structure as the containing shell disintegrates. DNA, in general, looks like strands and coils of rope lacking any higher levels of structure. RNA on the other hand appears as complicated, linear sequences of self-involved secondary structure. Sometimes, however, the distinction is not entirely clear and further evidence may be needed to show whether a filament or strand or complex is DNA or RNA through the use of specific enzymes.

In investigating virus infected cells and viruses engaged in the infection of host cells, occasionally virus can be observed passing their nucleic acid into the host cell. Sometimes it is possible to infer mechanistic features of DNA or RNA delivery. **Fig. 14** presents some examples. Most familiar is the injection of DNA into a host bacterial cell by a tailed bacteriophage. **Fig. 14(a)** shows a cyanophage with its head still filled with DNA and its tail sheath fully extended. In **Fig. 14(b)** another cyanophage has a fully compressed tail sheath, the head now an empty shell, the nucleic acid has been ejected, and all around the phage are strands of its DNA.

Fig. 14(c) shows a remarkable event captured by AFM. A mimi virus core is seen expelling an encapsidated, membrane sac containing its DNA through the now wide open, fivefold mouth. The opening is produced by the dissolution of the mimi star structure (**Fig. 10(b)**) and the folding back of the leaves of the vertex. In **Fig. 14(d)** a near totally disassembled vaccinia core is expunging its massive load of DNA. In **Fig. 14(e)** the RNA of a SARS virion, still heavily complexed with proteins, forms a circular,

Fig. 15 *Viral assembly.* (a) and (b) are AFM images showing the simultaneous production of icosahedral heads and helical tails of future cyanophage within a single bacterial cell. (c) and (d) are AFM images of “virus factories” found in mimi virus infected amoeba cells. The factories each produce hundreds of virus particles.

distinctive structure as its outer shell dissolves into pieces. These circular forms later restructure as the “pinwheel” in **Fig. 13(e)**. In **Fig. 14(f)**, virions of the very small satellite tobacco mosaic virus (T-1, 17 nm diameter), treated lightly with phenol, are seen with striking synchrony extruding their single stranded RNA complements that contain but a single gene.

Viral Assembly

In rare instances, when host cells that are actively engaged in producing virus are disrupted by mechanical or chemical means, the actual production and/or assembly of particles can be observed. **Fig. 15** presents two examples. In **Fig. 15(a)** and **(b)** are infected cyanobacterial cells in the process of manufacturing bacteriophage. Apparent in the images is the separate construction in the cytoplasm of icosahedral heads and helical tails. It is not, however, apparent from the observations how the two substructures are subsequently brought together and joined, a process on the nanoscale level that must resemble the coupling of boxcars in composing a train.

Of great interest in the genesis of large, complex viruses is the role of “viral factories” that, like a bubbling fountain, gush out masses of newly formed virus particles. **Fig. 15(c)** and **(d)** are AFM images of “virus factories” producing, at their surfaces, remarkable amounts of mimi virus cores. The prolific factories are found in substantial numbers in the interiors of infected amoeba host cells that have been mechanically disrupted.

Historical Background

The first direct visualization of virus particles, an electron micrograph of tobacco mosaic virus, came half a century after the existence of organisms smaller than bacteria was established (Kausche *et al.*, 1939). The advent of electron microscopy was shortly followed by a period of discovery whereby viruses related to many diseases were observed for the first time: variola, vaccinia and varicella, and poliovirus (Nagler and Rake, 1948; Van Rooyen and Scott, 1948; Reagan and Brueckner, 1952). However, during this period resolution was limited to gross particle shapes, often distorted due to chemical fixation and negative staining of the virus prior to imaging in the electron microscope. Embedding biological samples in ice was a critical advance, preserving high resolution information that is lost in the air-dried state (Adrian *et al.*, 1984; Taylor and Glaeser, 1974). While vitrification traps biological molecules in a thin film of amorphous ice, electron micrographs of these particles are inherently limited to low signal due to the sensitivity of biological molecules to radiation damage imparted by the electron beam. Because of the large depth of field in the electron microscope, each micrograph is a projection through the specimen, yielding 2D information (De Rosier and Klug, 1968). While direct observation of virus particles in 2D micrographs is useful for many applications, such as rapid diagnosis of clinical samples from virus outbreaks, the true power of cryo-EM relies on statistical averaging of many particle copies and interpretation of high-resolution 3D information (Kapikian *et al.*, 1972; Johnson *et al.*, 1977; Chiu *et al.*, 1997).

A 3D density map of the specimen can be generated from a set of particle views in different orientations. Before averaging the contrast transfer function (CTF) information, each projection image needs to be deconvoluted for its defocus setting. The averaging of multiple, equivalent copies of the molecule in a specific view serves to increase the signal-to-noise ratio of that orientation (Crowther *et al.*, 1970; Frank, 1975). Given sufficient views of a particle taken with enough defocus settings, a 3D volume can be reconstructed from 2D images without missing information. The combination of vitrification (to preserve high-resolution features of the specimen), large particle numbers (to overcome low-SNR in each image), and methods to reconstruct a 3D density map from multiple particle orientations, allowed for the first sub-nanometer reconstruction of tobacco mosaic virus by cryo-EM (Jeng *et al.*, 1989). The first 3D reconstructions of single particles to reach sufficient resolution to model the capsid polypeptide backbone utilized high-symmetry specimens, namely the icosahedral viruses epsilon-15, cytoplasmic polyhedrosis virus and rotavirus (Yu *et al.*, 2008; Jiang *et al.*, 2008; Zhang *et al.*, 2008). Each icosahedral virus particle has significant protein and nucleic acid mass (typically tens of megadaltons), with protein capsids arranged in 60 identical asymmetric units. A combination of electron scattering mass and structural symmetry allows for accurate determination of particle orientations and significant averaging power. For many of the same reasons that viruses proved ideal specimen in reaching near-atomic resolution for single-particle cryo-EM, sub-volume averaging of viruses is leading the progression of *in-situ* cryo-electron tomography (cryo-ET) to increasingly higher resolutions today (Schur *et al.*, 2016).

In this article we first describe cryo-EM methods for solving and analyzing virus structure at near-atomic resolution. Next, we describe information within cryo-EM maps of different viruses and discuss the implications for such processes as virus assembly, genome packaging, infection, and host-interactions. Finally, we briefly describe exciting recent advancements in directly visualizing stages of the virus life cycle *in-situ* using cryo-ET.

Cryo-EM at Near-Atomic Resolution

In recent years, many virus morphologies have proven amenable to high-resolution structure analysis by cryo-EM (Fig. 1). The vast majority of these PDB-deposited structures utilize global symmetry inherent in the particles during the image processing steps. Sorting of conformational heterogeneity both between particle populations and within individual particles has proven a valuable method to increase resolution of virions lacking exact icosahedral symmetry. The rapid increase of near-atomic resolution structures in the field can be attributed to several advances in both experimental and computational techniques.

Data Collection and Image Reconstruction

The prospects of achieving near-atomic resolution structure of viruses by cryo-EM now largely relies on a few notable factors: particle count, particle homogeneity, structural flexibility, particle size and ice thickness. Much of the recent proliferation in near-atomic resolution structures of virus capsids can be attributed to the improved quality of images recorded on a new generation of direct electron detectors with increased detective quantum efficiency (DQE) and high frame-rate acquisition of “movie-mode” images (McMullan *et al.*, 2009). The improvement in detector DQE corresponds to a higher SNR contained in each image, boosting contrast and increasing the accuracy of particle alignment during the orientation refinement steps (described below). Additionally, images collected as a “movie” of sub-frames allow for alignment of the same specimen area in each individual frame

Fig. 1 Structures of diverse virus capsids have been solved by cryo-electron microscopy to near-atomic resolutions. Representative examples include plant viruses brome mosaic virus (EMD-6000, PDB-3J7L) and tobacco mosaic virus (EMD-2833, PDB-4UDV), bacteriophage P22 (EMD-8606, PDB-5UU5), and significant human-disease causing agents Zika virus (EMD-8116, PDB-5IRE) and the capsid-like assembly of Ebola virus (EMD-7343, PDB-6C54) (Wang *et al.*, 2014; Fromm *et al.*, 2015; Hryc *et al.*, 2017; Sirohi *et al.*, 2016; Su *et al.*, 2018). At sub-4 Å resolution, an atomic model of the capsid polypeptide (dark blue) can be reliably fit into the density (gray). Virus capsids to scale.

to correct for beam-induced movements of the stage and/or specimen, further improving image SNR and resolution (McMullan *et al.*, 2009; Wang *et al.*, 2014; Brilot *et al.*, 2012).

Single-particle image processing pipelines used to compute cryo-EM density maps involve assessing micrograph quality, selection of particles, image defocus estimation and correction, particle orientation estimation and refinement, image reconstruction and map validation. A large number of different software packages, often utilizing different computational techniques, have been used to solve 300+ virus structures between 1.9 and 4.0 Å resolution (Tan *et al.*, 2018). Recently, additional methods such as 3D-classification of particle conformations, refinement of sub-particle orientations and correction of Ewald-sphere effects for large viruses have been used to overcome limitations in the conventional data processing pipelines (Walls *et al.*, 2016; Wolf *et al.*, 2006). Moreover, the computational capabilities of facilities with large computing clusters has allowed for a remarkable increase in both throughput of cryoEM structures and the ability to handle large datasets that now routinely reach millions of individual particle images for a single experiment.

In addition to the microscope hardware and computational improvements, success of single-particle cryo-EM experiments in reaching near-atomic resolutions is also dependent on the specimen preparation. Since the invention of vitrification of biological samples, as first demonstrated with virus particles, the process of plunge-freezing thin films of specimens into liquid ethane has remained incredibly consistent (Vogel *et al.*, 1986). Today, a variety of commercial plunge-freezer apparatuses are available for this task, allowing for high throughput of cryoEM grids prepared with different parameters. To complete a successful sample preparation, the investigator is responsible for optimizing the sample purity and distribution of particles within image acquisition areas, as well as optimizing thickness of the embedding ice. Recently, there have been major innovations for measuring and optimizing ice thickness, both before vitrification and during cryo-EM imaging (Rice *et al.*, 2018; Dandey *et al.*, 2018). In addition, the development of techniques for rapid application of sample has shown promise for improving particle distribution, capturing transient reaction intermediates, reducing denaturing effects of the air-water interface, and limiting the amount of specimens needed for cryo-EM experiments (Dandey *et al.*, 2020).

Resolution in cryo-EM maps is determined by computing the Fourier-shell coefficient between two independent half-maps, at a specific threshold (0.143), termed the “gold-standard” procedure (Henderson *et al.*, 2012; Scheres and Chen, 2012). This is practically achieved by randomly splitting the data into two random sets at the beginning of the data processing procedure and computing two independent reconstructions. The resolution is then a measure of the reproducibility of features in the two maps. As resolution improves, the amount of biological information that can be extracted from the map increases. At sub-nanometer resolution, (6–9 Å), protein subunit boundaries can be defined, while β -strands appear as continuous slabs and helices as flat “sausages”. At 4.5 Å resolution and better, β -strands are separated, the pitch of α -helices can be seen, and some bulky side chains become apparent. An atomic model, representing the full atomic coordinates of the protein, can be fit into the density map by

taking stereochemical constraints and minimization of atomic clashes into consideration. Typically, at 3.5 Å resolution, the C α polypeptide backbone can be traced and most side chains accurately positioned with proper stereochemistry (Hryc *et al.*, 2017). Interpretation of the atomic model can be extended beyond peptide and side chain placements at resolutions better than 2.8 Å, where densities such as bound waters, lipids, and sugars can be accurately modeled with proper stereochemistry relative to nearby side-chains, without the need for orthogonal validation experiments (Roh *et al.*, 2020).

Interpretation of Near-Atomic Resolution Maps

Side Chain Interactions and Virus Assembly

Many viruses utilize conformational changes between morphogenic states as part of their assembly and maturation pathway. This is exemplified by DNA phages that transition from a genome-free “procapsid” state to a final, genome-packaged, metastable virion through a series of conformational rearrangements in the major capsid protein (Guo *et al.*, 2014; Jiang *et al.*, 2003). Viruses of the enveloped ssRNA family *Flaviviridae* begin as rough, spiky particles composed of E glycoprotein surface trimers and finish as a smooth coat of E proteins arranged as dimers in herringbone pattern (Hryc *et al.*, 2017; Zhang *et al.*, 2007; Zhang *et al.*, 2013). When possible, the purification of viruses in distinct assembly states allows for comparison of global morphologies and observation of subtle changes in polypeptide conformations and side-chain interactions essential to the structural transitions. Classification of particle conformations in 3D during data processing offers the potential to separate distinct populations and solve structures of multiple virus assembly states in a single experiment without the need for absolute sample homogeneity.

A striking example of the transition between virus conformations is explored in the near-atomic resolution cryo-EM maps of phage P22 procapsid and mature virion. Comparison of sub-nanometer structures first revealed the procapsid is more rounded in global conformation relative to the expanded, more angular virion capsid (Scheres, 2016; Chen *et al.*, 2011). At 3.8 Å, the C α backbone models of gp5 coat protein and gp8 scaffolding protein reveal electrostatic interactions between the negatively-charged N-arm region of gp5 and positive charged C-terminus of gp8. In the mature virion model of gp5, derived from the 3.3 Å resolution map, the N-arm region of every subunit forms a β -sheet with a protomer in a neighboring asymmetric unit, and the neighboring subunits in the same asymmetric unit form salt bridges (residues Glu5 and Glu15) with residues Lys31 and Arg42, respectively (Hryc *et al.*, 2017). The rearrangement of the flexible gp5 N-terminal arm from interacting with scaffold gp8 in the procapsid state to then stabilizing inter-subunit interfaces in the metastable virion, is proposed to serve as a driving signal for global capsid maturation.

Beyond Global Symmetry

The widespread utilization of icosahedral capsids across diverse viral lineages is a striking display of structure convergence to maximize evolutionary fitness. It is only when taking a more detailed view of these particles that the structural asymmetries essential to individual viral life cycles are revealed. Until now, discussion has been limited to averaging of icosahedral viral capsids, where 60-fold symmetry is applied during reconstruction to achieve near-atomic resolution structure. In icosahedral viruses, structural gene products range from arrangement in perfect symmetry to quasi-equivalence and full asymmetry. In addition, structural proteins are often incorporated into the mature viral particles or structural intermediates at sub-stoichiometric amounts relative to the major capsid proteins. To resolve these features, the highly accurate orientation of a single asymmetric unit in the icosahedral capsid typically serves as a starting point for searching over all possible asymmetric orientations and choosing the correct one based on alignment to a symmetry-breaking feature. The use of so-called “expanded symmetry”, in combination with 3D classification on focused regions (available through a popular image reconstruction software called Relion), has proven extremely valuable in resolving complexes small in size and/or with different symmetries relative to the protein capsid (Scheres, 2016). The relationship between symmetry and resolvability in capsid structures is exemplified by viral gene products such as portal and tail complexes in DNA viruses and viral genomes in RNA viruses, while local symmetry of membrane glycoproteins in pleomorphic enveloped viruses aids their study at near-atomic resolutions.

Symmetry Mismatch in DNA Portals

Double-stranded DNA (dsDNA) bacteriophages package and often eject pressurized DNA through a portal complex located at one unique vertex on the virus capsid. The portal connector hub forms an attachment site for phage tail machinery and closure proteins. Phage portals and tail complexes show great variability in morphology and complexity: some are mostly-contained inside of the capsid shell while others are long extensions that greatly exceed the length of the capsid head. Because the portal is located at a single five-fold vertex on the capsid, traditional icosahedral-reconstruction will fail to resolve this non-icosahedral component. Instead, the orientation of the tail relative to the dominant icosahedral capsid must be found. A typical asymmetric reconstruction of the virus capsid, required to resolve the position of the unique portal, will contain 1/60th the signal at each asymmetric unit compared to an icosahedral-symmetrized reconstruction. It is the lack of cumulative signal that explains why asymmetric reconstructions routinely fail to reach the resolutions achieved in icosahedral reconstructions of epsilon15 and P22 phages (Chang *et al.*, 2006; Jiang *et al.*, 2006).

Fig. 2 Protein machines responsible for DNA packaging and exit are located at one unique vertex on the virus capsid in (A) bacteriophage P22 (EMD-1222) and Herpes simplex virus 1 (HSV-1) (EMD-9864). The dodecameric portal assemblies, breaking the icosahedral symmetry of the capsid, are revealed by asymmetric reconstructions (Chang *et al.*, 2006; McElwee *et al.*, 2018) (Liu *et al.*, 2019) (Chang *et al.*, 2006; McElwee *et al.*, 2018). With further focused-classification techniques, the structure of all components of the HSV-1 portal complex were determined at sufficient resolution to build a (B) model of the polypeptide-backbone of each protein and resolve interactions with the dsDNA (PDB-60D7) (Liu *et al.*, 2019).

To overcome the difficulty of aligning virion particles without imposed icosahedral symmetry, the predominant strategy is to use the coordinates of an icosahedral refinement, rotate the particle to each of the 60 equivalent icosahedral positions, and find the one position that best matches an asymmetric model without refining the orientation. In some cases, where the tail provides significant signal, the orientation of the tail complex can be directly found without using the capsid orientation, or by searching over a constrained orientation space using the above procedure as a starting point. The first visualizations of portal complexes in asymmetric reconstructions revealed conclusively that the portal is organized as a dodecamer, typically with a fixed orientation relative to the capsid (Liu *et al.*, 2010; Tang *et al.*, 2008; Jiang *et al.*, 2006). Symmetry mismatches often exist between the portal protein and external tails and/or internal connector stacks (Chang *et al.*, 2006; Guo *et al.*, 2013). In P22 phage, the asymmetric reconstruction of the unique portal revealed a sixfold hexamer tail attached to a dodecamer connector complex, while a long C-terminal tail inside the capsid appears to serve a similar function as an internal connector stack (Chang *et al.*, 2006).

The insights into DNA packaging and genome egress gained from model bacteriophages can be extended to eukaryotic systems wherever shared structural mechanisms exist. One such example is the conservation of the characteristic HK-97 protein fold and capsid assembly pathway between prokaryote-infecting tailed bacteriophages (*Caudoviridae*) and eukaryote-infecting herpesviruses (*Herpesviridae*) (Fig. 2). Where no sequence similarity could predict common ancestry, cryoEM maps of phage P22 and HSV-1 revealed common capsid protein fold and virion architecture (Baker *et al.*, 2005). Interestingly, a protein portal was subsequently discovered in HSV-1 B capsids, answering the outstanding question of why the Herpes capsid is located asymmetrically in close proximity to one side of each virus envelope (Rochat *et al.*, 2011). Similarly, following the elucidation of an internal portal complex in model phage PRD1, re-evaluation of the structurally-related human Adenovirus resulted in identification of a unique icosahedral fivefold vertex by immunogold labeling of protein IVa2 (Ahi *et al.*, 2017; Strömsten *et al.*, 2003).

The study of portal complexes in the context of the native particle by cryo-EM has revealed common folds, common ancestry among lineages of DNA viruses infecting prokaryotes and eukaryotes, and common strategies for incorporating symmetry mismatches into functional protein machines. The study of portals in intermediate states has also led to a model whereby these complexes act as essential nucleators of procapsid assembly. Current data processing techniques offer the potential to better understand portal assemblies and portal-genome interactions at near-atomic resolutions (Liu *et al.*, 2019; McElwee *et al.*, 2018).

Envelope Glycoproteins

Enveloped viruses utilize membrane-anchored proteins that mediate cell entry *via* binding to receptor molecules on the host cell surface and facilitating fusion between the viral and host membrane bilayers. These membrane protein assemblies are often visible in electron micrographs of enveloped virus particles, existing as distinctive “spikes” protruding outward from the virus surface. For

Fig. 3 Cryo-EM structure of a human coronavirus S trimer computationally extracted from intact particles. (A) Representative cryo-EM micrograph of purified human coronavirus NL63 (HuCoV-NL63) particles with marked positions of spike (S) trimers (white circles). (B) Reconstructed cryo-EM map of HuCoV-NL63 S trimer in closed, pre-fusion conformation as side and top views with glycans depicted (yellow).

many viruses, these envelope proteins are heavily glycosylated, with N- or O-linked glycan species serving critical functions in protein folding and assembly, cellular tropism and immune evasion. Due to the pleomorphic nature of the lipid envelope, enveloped viruses generally lack global symmetry useful for determining highly accurate orientations of virus capsids as previously discussed. Instead, structural studies of envelope glycoproteins reaching near-atomic resolution typically require *in vitro* expression and purification of the soluble protein sequence exterior to the viral membrane (Lee *et al.*, 2016; Walls *et al.*, 2016). In many cases, stabilizing mutations are required to produce suitable glycoprotein complexes for these structural studies (Kirchdoerfer *et al.*, 2018; de Taeye *et al.*, 2015). Cryo-ET of membrane viruses and averaging of envelope proteins computationally extracted from tomograms of virus particles allows for study of these complexes *in-situ*, both representing the native chemical state of the glycoproteins and providing spatial context relative to other components of the virion. While the resolvability of these glycoprotein subtomogram averages are typically limited to 5–10 Å due to small particle size, conformational variability and loss of high-resolution information during tilt series acquisition, recent developments in subtomogram averaging show promise in pushing on to higher resolutions.

The study of envelope glycoproteins in the native state by single particle cryo-EM is exemplified by structures of human coronavirus spike (S) trimers that are computationally extracted from images of intact virions (Ke *et al.*, 2020; Zhang *et al.*, 2020). Previously, *in vitro* structural studies of purified coronavirus S trimers, the major focus of current vaccine design, relied on protein expression of the S1/S2 “crown” region stabilized by introduced mutations in the S2 fusion machinery (Kirchdoerfer *et al.*, 2018; Pallesen *et al.*, 2017; Wrapp *et al.*, 2020). However, in the study of human alphacoronavirus NL63 (HuCoV-NL63), full-length S trimers, including the C-terminal stalk connecting the crown to viral envelope, are clearly visible in micrographs of vitrified virus particles (Fig. 3) (Zhang *et al.*, 2020). In this case, the sample preparation was performed without utilizing any of the chemical fixatives required for handling and freezing of more pathogenic coronaviruses. Surprisingly, though the majority of extracted particles are “side” views projecting outward from the viral envelope, the c3-symmetric average of the S1/S2 “crown” region in the closed, pre-fusion conformation reached 3.4 Å resolution. This exciting result displays the potential of single particle cryo-EM methods to resolve near-atomic resolution structures of glycoprotein complexes in the context of the virus particle, without the need for *in vitro* purification or mutations. In the near future, this method will likely be applied to additional viral envelope proteins, producing *in-situ* structures at resolutions suitable for drug optimization and vaccine design studies.

Genome Structures

Due to the dominant, symmetric signal provided by viral protein capsids, many insights into viral assembly from cryo-EM structures have naturally involved capsid protein-protein interactions and changes in polypeptide conformations during capsid maturation. An underappreciated aspect of viral assembly pathways is the encapsidated nucleic acid genome and its interactions with the protein capsid. In dsDNA phages of family *Podoviridae*, including phage P22, interactions between DNA and an

Fig. 4 Cryo-EM and asymmetric reconstruction allows for the visualization of viral genomes *in situ*. The (A) cryo-EM density map of phage MS2 (EMD-8397) reveals a single copy of maturation protein on the viral capsid, providing a strong asymmetric density (Dai *et al.*, 2017). The (B) cut-open view of the virion reveals the entirety of the viral genome (blue), where the 3' end interacts with the maturation protein in a relatively fixed orientation. The genome density map revealed the short- and long-range genomic RNA interactions as well as contacts with the interior surface of the capsid protein.

asymmetric portal complex state are proposed to induce a conformational change in the portal proteins and signal an end to genome packaging (Lokareddy *et al.*, 2017). Instead of injecting genome into preformed protein shells, RNA viruses typically co-assemble with the genome. For viruses of family *Orthoreoviridae*, interactions between 10 ssRNA gene segments within the host cytosol are believed to facilitate encapsulation of the viral genome by an inner protein shell at the earliest point of assembly (Borodavka *et al.*, 2017).

The structural organization of the viral genome can be best resolved in cases where it exists in a fixed conformation relative to an asymmetric feature on the virus capsid (Fig. 4). This was exhibited in the stunning maps of ssRNA phages MS2 and Q β , where the majority of the full RNA genome could be modeled into sub-nanometer resolution density maps based on RNA base-pairing constraints (Dai *et al.*, 2017; Gorzelnik *et al.*, 2016). In both cases, the conformationally homogenous ssRNA genome exists in a fixed orientation relative to a significant asymmetric protein density on the capsid surface termed “maturation protein.” In addition to revealing the *in situ* organization of the viral genome, these maps allowed the identification of interactions between genomic secondary structure and recognition elements on the interior surface of the protein capsid. In less ideal cases where the genome is not organized relative to a strong asymmetric feature on the virus capsid, methods to subtract the symmetric capsid signal from each raw particle image and determine the asymmetric genome orientation from the remaining information have proven useful (Liu and Cheng 2015; Zhang *et al.*, 2015).

In-Situ Structural Virology

Cellular Electron Cryotomography

As discussed so far, the basis for single-particle averaging is the existence of a large number of equivalent molecules in distinct orientations. Many situations exist when the specimen of interest does not exhibit conformational homogeneity, particle numbers, or stability required for single-particle analysis: some of these cases include pleomorphic enveloped virions, virus assembly and disassembly intermediates, and virus-induced subcellular structures, among others. When presented with these challenges, tomography is the only way to generate 3D structures of individual molecules. In cryo-electron tomography (cryo-ET), a series of projection images are collected by tilting the specimen and combining the resultant “tilt-series” into a 3D volume (Crowther *et al.*, 1970; De Rosier and Klug, 1968). In contrast to individual projection images, these reconstruction volumes provide valuable information regarding the 3D orientation and spatial organization of features. This 3D information is especially useful in applications such as analyzing glycoprotein assemblies in pleomorphic virus envelopes, asymmetric virus-receptor interactions, and virus intermediates in the context of the host cell.

The structural information within a reconstructed tomogram is limited by three notable factors: low signal in each tilt image to limit accumulated electron dose often compounded by thick specimen, missing information due to mechanical limitations in the microscope stage (termed the “missing wedge”), and accuracy of alignments between each successive tilt image prior to reconstructing a 3D volume (Lučić *et al.*, 2013). Recovery of high-resolution information from individual features, the “N of 1” situation, has not been achieved without the use of averaging (Kaelber *et al.*, 2017). Because the entire tomographic field of view is reconstructed in 3D, homogenous copies of an object or consistent substructures within heterogenous objects, can be extracted and aligned to generate a 3D density map.

Study of native viral intermediates is often limited by the fast dynamics of assembly and sensitivity of these conformations to purification. For this reason, stable genetic mutants that resemble the corresponding transient intermediate state are often studied *in-vitro* to gain insight into the cellular processes. An elegant solution to this problem was provided in the study of native Syn5 dsDNA phage assembly *in situ* (Dai *et al.*, 2013). Whole-cell imaging of cyanobacteria containing Syn5 intermediates using Zernike phase plate for increased low-resolution contrast allowed for visualization of native phage progeny within the cytosol (Dai *et al.*, 2014). Analysis of these progeny *via* extraction and 3D classification resulted in the identification of five distinct Syn5 conformations. This provided conclusive evidence of an assembly order in which Syn5 first acquires its DNA genome through a portal at one icosahedral vertex, a tail is added to the portal vertex, and finally a protein complex termed the “horn” is attached to the vertex opposite the tail to complete the virion assembly process. In this way, cryo-ET studies of virus infection and assembly in whole bacteria cells offer incredible amounts of spatial and temporal information regarding the virus replication cycle and viral infection-induced effects on the host in the natural environment.

Analysis of human cells by cryo-ET is limited to the areas where the electron beam can penetrate the sample. For this reason, cell lines that spread on the cryo-EM grid surface are preferred, allowing for visualization of features deeper into the cell body. With many enveloped viruses, rich information conveniently exists at the plasma membrane, where particle budding and assembly occurs for a number of ssRNA virus families including *Retroviridae*, *Filoviridae*, and *Alphaviridae*. Cryo-ET imaging of human u2os cells infected with *Chikungunya* (CHIKV) virus of family *Alphaviridae*, and subsequently treated with a potent human anti-CHIKV antibody, provided a stunning visual understanding of the mechanism of antibody neutralization at the cell surface (Fig. 4) (Jin *et al.*, 2018). Antibody C9 can be seen bound to glycoproteins exposed at the cell surface, while pleomorphic nucleocapsids containing the ssRNA genome are trapped beneath the membrane in the cytosol. Further, the close proximity of RNA replication spherules to the sites of inhibited virus budding provide valuable information related to the CHIKV assembly pathway starting with positive-strand RNA synthesis and progressing to genome packaging, virus assembly and budding at the plasma membrane (Fig. 5).

Due to the high copy number of progeny virus in infected cells, virus assembly events in the cellular context are most easily located for native imaging by cryo-ET. However, it is also possible to study virus infection of host cells, though capturing this process often requires significant searching of the cryo-EM grid and a sharp eye! In the case of HSV-1 infection at the plasma membrane, distinct 3D entry intermediates revealed the morphological changes in virus and plasma membrane at stages of virus attachment, glycoprotein-driven membrane fusion and entry (Maurer *et al.*, 2008). With a sufficient number of captured events, it is possible to gain insights into the reaction dynamics of transient processes. Correlating the occupancy of distinct 3D states with the underlying process dynamics remains a rich area of development to bring *in situ* cryo-ET together with molecular simulations. Identifying points of dynamic pauses or rate-limiting steps in virus assembly and infection by *in situ* cryo-ET offers the potential to target these intermediate structures *via* antiviral strategies (Sutton *et al.*, 2020).

While cryo-ET analysis of human cells is mostly limited to the cell surface, advancements in focused ion beam (FIB) milling of thin cell lamella under cryo-conditions offers the potential to look deep within the cell at areas of interest at medium resolution

Fig. 5 Neutralizing antibodies (Nabs) bind to Chikungunya virus (CHIKV) glycoproteins exposed on the cell surface to block budding and egress of nascent virions. The blocking of viral egress is an additional Nab function beyond classical entry inhibition. Electron cryotomography imaging of CHIKV-infected human cells *in situ* reveal (A) budding-arrested CHIKV nucleocapsids docked to the plasma membrane in the Nab-treated condition (Jin *et al.*, 2018). (B) Automated annotation of cellular features using a convolutional neural network reveals the arrested nucleocapsids (yellow), membrane (light blue), actin filaments (purple), microtubules (cyan), CHIKV RNA replication spherules (green) and Nab C9 (orange) (Chen *et al.*, 2017). Scale bar 100 nm.

(Wu *et al.*, 2020). Locating the position of fluorescent-tagged virus protein and correlating to the position on the cryo-EM grid within the microscope prior to imaging offers the potential to study events such as enveloped virus assembly and genome replication on internal membranes, viral fusion in endosomes, and disassembly and transport processes in the cytosol and nucleus. Recent developments in cryo-ET, including the use of phase plates for improved image contrast near-to-focus, FIB milling areas of interest, and a renewed interest in high-voltage electron microscopes and detectors, offer the potential to push resolution of specimen in a cellular context to near-atomic resolutions.

Introduction

Viruses are parasites which hijack and depend on cellular functions for their own replication, indeed, the viral replicative cycle obligatorily takes place inside a host cell. Therefore, studying viruses in the cellular context is the most biologically relevant way to study the processes occurring during viral infection. The viral replication cycle can be generalized to the following steps: attachment, entry, replication, assembly and release. Some viruses also undergo a maturation step. All these steps are amenable to imaging by electron microscopy, using one or more techniques.

The development of electron microscopy contributed significantly to the advancement of virology (Kausche and Ruska, 1939), as viruses are beyond the diffraction limit of light microscopy. That being the case, the evolution of virology has gone hand-in-hand with advances in electron microscopy. In fact, electron microscopy was and still is used as a powerful diagnostic tool in the clinical setting, in some cases capable of identifying an etiological viral agent at the genus level (Goldsmith, 2014).

Electron microscopy relies, as the name implies, on electrons as the illumination source. While electron microscopy can yield a wealth of information at nanometer and subnanometer levels of detail, it also has limitations. The electron beam path in the microscope column needs to be a vacuum. As a result, an ultra-low pressure is present inside the column and, without preventative measures, this would cause evaporation of any water that is present in the sample. For this reason, the sample needs to be treated to withstand the vacuum. The two main kinds of treatment for this purpose are (1) chemical fixation followed by dehydration, resin embedding and (2) physical-fixation/cryo-immobilization (which may or may not be followed by freeze substitution, resin embedding). Both methods are discussed in the following sections, and, together, they divide the field of electron microscopy into two major “flavors”: room temperature-electron microscopy (RT-EM) and cryo-electron microscopy (cryo-EM).

Electrons also have a very limited penetration ability. Therefore, if the specimen is to be analyzed by Transmission Electron Microscopy (TEM), it must be very thin, usually less than 300 nm thick (Lučič *et al.*, 2013). Cell thickness varies from cell to cell and from one point of the cell to another (e.g., the nucleus is much thicker than filopodia). Depending on the cellular region of interest, thinning of the specimen may be required. This can be achieved by microtome sectioning or ion-beam milling of the sample into ultrathin slices 70–200 nm thick (Romero-Brey and Bartenschlager, 2015).

In the case of a virus-infected cell, the ultrathin sections may be rich in information but must be considered in the context of the much larger cellular volume; this can be difficult. Further, 2D projection images recorded from ultrathin sections may be hard to interpret and even mis-interpreted. As an illustrative example, for many years, it was debated whether HIV can bud into endosomes in infected macrophages or if HIV exclusively buds from the cell plasma membrane. It took 3D electron microscopy to finally settle the matter by describing a new type of compartment, Intracellular Plasma-Membrane Connected Compartments (IPMCs) which may resemble endosomes in 2D cross-section micrographs, but are in fact connected to the plasma membrane through complex membrane folds (Bennett *et al.*, 2009; Welsch *et al.*, 2011).

Several microscopy techniques offer 3D representation of an imaged object. In serial sectioning EM, successive microtomy slices of a sample are imaged and stitched together to reconstruct a thicker volume (Sjostrand, 1958). Serial block face imaging works on a similar concept, but instead of having a slice ribbon mounted on an EM grid, the sample block is mechanically sliced directly inside the microscope with a microtome, and the newly exposed surface is imaged (Denk and Horstmann, 2004). In FIB/SEM, the same principle is applied, instead of using a microtome, successive surface layers are exposed by Ion Abrasion (Heymann *et al.*, 2006). These 3D electron imaging techniques are applied to study biological samples at different spatial scales, which can be combined and integrated with optical imaging modalities through correlative light and electron microscopy (Jun *et al.*, 2011; Moser *et al.*, 2019). Here we focus discussions on electron tomography.

Fig. 1 From a tilt-series to a tomogram. (A) In the electron microscope, a fixed sample (either in vitreous ice or resin) is imaged multiple times, each time tilted to a different and known angle. (B) This collection of images is called a tilt-series. (C) From this series of projection images, a 3D object, called a tomogram, can be calculated (Koning *et al.*, 2018).

Electron tomography is one of many 3D imaging techniques, by which the same region of interest is imaged multiple times, but each time at a different angle, resulting in a tilt-series. These images can be processed computationally to produce a 3D object that represents the original sample volume (Crowther *et al.*, 1970) and is called a tomogram (Fig. 1).

Limitations of electron tomography include electron radiation damage and the missing-wedge effect (Radermacher, 1988). Since the same region is imaged multiple times, at different specimen tilt angles, the accumulated electron dose may induce alterations to the structures imaged. For that reason, careful electron dose management is necessary, particularly in cryo-fixed samples (Hagen *et al.*, 2017). The missing wedge is an artifact of electron tomography. It is a product of both the low penetrating power of electrons and limited mechanics of the sample stage. As the sample is tilted, the sample becomes increasingly thicker, to a point where the transmitted signal becomes too low. In addition, microscope sample stages are typically limited to 70 degrees tilting due to stage stability and the limited space available inside the microscope column. Due to the missing wedge problem, the 3D representation of the imaged object is not perfect, but elongated in the direction parallel to the beam path (Radermacher, 1988).

Sample Preparation

As mentioned, the manner in which a sample is fixed and treated to withstand the vacuum of the microscope column divides electron tomography into two types: Room-temperature electron tomography and cryo-electron tomography. This division is not always mutually exclusive. Some techniques, such as High Pressure Freezing and Freeze Substitution require initial cryo-fixation of the sample, but the imaging is done in room-temperature (after the sample is freeze-substituted to resin and sliced).

Chemical Fixation

Chemical fixation uses cross-linking chemical reagents (formaldehyde and glutaraldehyde are the most commonly used) to stabilize the biological components in the cell. Traditionally, to enhance contrast and improve interpretability of images, stains containing heavy atoms (e.g., Uranium, Osmium, Molybdenum) are used. After fixation, the water present in the sample needs to be replaced by resin, allowing the sample to withstand the vacuum. The resins used in electron microscopy (e.g., epoxy) are very hydrophobic, so an intermediate step of sample dehydration is necessary. The sample undergoes a series of incubations with solvents at increasing concentrations, to gradually replace all the water in the sample with solvent (most commonly ethanol or acetone). The solvent is then replaced by the resin, also in step-wise fashion. After polymerization of the resin, the sample block is sectioned in thin slices (70–300 nm thick), attached to an electron microscopy grid, and imaged in the electron microscope (Griffiths, 1993). Although this time-consuming and labor-intensive procedure can introduce artifacts in the samples and/or destroy some sensitive ultrastructural details (Small, 1981), much of what is currently known in virology was the product of this technique, and the field of virology owes a lot to it.

Cryo-Immobilization

In the last three decades technological advances have enabled the imaging of biological specimens in their near-native state in the absence of stains, especially the development of cryo-fixation through vitrification and cryo-electron microscopy (cryo-EM) (Taylor and Glaeser, 1976; Dubochet and McDowell, 1981). At very low temperatures (below -150°C), the issue of water evaporation in the vacuum of the microscope column is eliminated, and ice serves as fixative. However, only ice in a vitreous form can preserve a biological sample in a near-native state; formation of crystalline ice perturbs the ultrastructural details in the sample. Vitrification of thin specimen ($<2\ \mu\text{m}$) can be achieved by rapid plunge-freezing into liquid ethane or a liquid ethane/propane mixture (Dubochet and McDowell, 1981).

Vitrification of thicker and larger sample volumes (μm^3 to mm^3), such as tissue, can be achieved by High Pressure Freezing (HPF) (Moor *et al.*, 1980). Such samples, therefore, need to be thinned prior to imaging in the electron microscope. This can be achieved by maintaining cryo-preservation using either CEMOVIS (Cryo Electron Microscopy of Vitrified Samples) (Hsieh *et al.*, 2002) or cryo-FIB/SEM milling (Marko *et al.*, 2007). Alternatively, the sample may be slowly dehydrated by a technique called freeze substitution (FS), then resin-embedded and sliced in plastic sections (Hawes *et al.*, 2007).

Room Temperature-Electron Tomography

In room temperature-electron tomography (RT-ET), heavy-metal stained sections of resin embedded sample are typically imaged (Romero-Brey and Bartenschlager, 2015). In this technique, a cell culture or tissue is chemically fixed, stained, dehydrated, resin-embedded and sliced. The slices are then mounted on an EM grid and loaded onto the electron microscope. Tilt-series are collected at the regions of interest and then computationally converted to tomograms (Fig. 2, top left panel). This technique allows imaging of any part of the cell or tissue. The judicious use of chemical fixatives and immunocytochemistry-friendly resins may preserve antigenicity of the sample and allows direct immunostaining and gold-labeling, enabling identification of target structures in the electron micrographs (Griffiths, 1993).

An extended version of RT-ET is serial tomography, where consecutive sections of a cell or tissue are imaged by ET and then combined to build a larger volume. This is a powerful technique as it combines the high-resolution ET and the possibility of reconstructing up to mm^3 of a sample. The sample may be chemically fixed or be processed by HPF/FS (High Pressure Freezing/Freeze Substitution) before resin embedding and sectioning.

The application of RT-ET is exemplified by imaging of virus infected tissues. In Kieffer *et al.*, 2017, the authors pursued multiscale imaging of gut-associated lymphoid tissue, the female reproductive tracts and spleens of humanized mice that had been infected with HIV (Kieffer *et al.*, 2017). By combining 3D immunofluorescence with electron tomography they described systemic viral spread during early infection. Apart from the wealth of environmental context contained in the tissue samples, such as the presence of blood vessels near infected cells in multiple tissues, or the collagen fibrils surrounding pools of viruses in spleen samples, the study also allowed observations regarding the timing and progression of tissue infection and the routes of HIV spread after the initial infection.

Cryo-Electron Tomography

In cryo-ET, the sample is held at a temperature below -160°C and the electron dose used for imaging is kept low (typically $60\text{--}120\ \text{e}^- \text{\AA}^{-2}$) to reduce radiation damage to the specimen. Since the sample is preserved and imaged in a frozen-hydrated state, no additional sample manipulation is necessary and little ultrastructural detail is compromised (McDowell *et al.*, 1989). Due to the absence of stain and the use of low electron doses, the contrast is poor. Nonetheless, the structural information is present in its entirety. If a tomogram depicts multiple copies of the same object, they may be computationally combined to enhance the information of the object of interest. This is particularly useful in virology. Viruses, as very simple pathogens, rely on small genomes that encode few ORFs (Open Reading Frames) but can use multiple copies of the same protein to build a larger structure. A good example of this is the viral capsid. Many copies of morphological building blocks (capsomers) assemble to form a protein shell that protects other viral components. Capsomers in a tomogram (or in multiple tomograms) can be averaged to produce a high-resolution depiction of the capsomer unit. This strategy may yield maps at near-atomic resolution (Himes and Zhang, 2018). This computational approach is called sub-tomogram averaging, and may be used not only for capsomers, but also in any other case where repeated units of the same structure are present and can be averaged, such as envelope spikes and viral portals (Cardone *et al.*, 2007; Liu *et al.*, 2008).

A major caveat of cryo-ET is that it is not amenable to direct immunofluorescence or gold-labeling. This could prevent unambiguous protein identification in macromolecular complex structures. Identification of protein components in cryo-microscopy may be achieved by comparative studies of wild-type and knock-out structures, or wild-type and fusion proteins. Extra density (in the case of fusion proteins) or an absence density (in the case of knock-out of a protein present in a macromolecular complex) can aid the identification of a target protein (Chang *et al.*, 2017). Another way of identifying a structure is to achieve a high-resolution map that enables confident fitting of existing atomic models.

Cryo-ET of Cell Periphery

The easiest way to comply with the requirement for thin samples is to study the thin periphery of cells. Fortunately, many stages of viral replication happen at or near the plasma membrane. Adhesion, fusion, and entry are early stages of viral replication that are

Fig. 2 Examples of different techniques used to study viruses in the cellular context. Top Left: Electron Tomography. Tomographic slice of an HIV particle budding from a T-lymphocyte. PM – Plasma Membrane, NE – Nuclear envelope, N – Nucleus. Inset shows a segment of the bud with a viral immature lattice in yellow and the lipid membrane in green (from [Ladinsky et al., 2019](#)). Top Right: Cryo-electron tomography at the cell periphery. Tomographic slice of an HIV core (arrow) inside a HeLa cell. A – actin filaments, MT – microtubule, V – vesicle, M – mitochondria, P – protein complexes. An enlarged view of the HIV core structure is in the inset. The viral core location was found using CLEM (Correlated Light and Electron Microscopy). Panel A shows the path taken by a fluorescently-tagged viral particle inside a HeLa cell (yellow tracing). The same region is imaged by cryo-EM at low magnification in panel B (from [Jun et al., 2011](#)). Bottom Left: Cryo-FIB/SEM. Tomographic slice of a cell lamella depicting the HSV-1 nuclear egress complex in the nuclear membrane intraluminal space. Black arrows point to inner nuclear membrane and white arrows to vesicle membranes. Nuc – Nucleus, ILS – Intraluminal space (from [Hagen et al., 2015](#)). Bottom Right: CEMOVIS. Tomographic slice of an HSV-1 infected Vero cell depicting a viral capsid budding into the perinuclear space (from [Hagen et al., 2015](#)).

well suited for study without the need of thinning ([Jun et al., 2011](#); [Riedel et al., 2017](#)), as are the late stages of assembly and release (when happening at the cellular membrane). These can be imaged directly in cells growing on EM grids ([Bharat et al., 2011](#)). Spread and dissemination (either between cells or within one cell, such as retrograde transport) may also be processes well-suited for study at cell periphery ([Ibircu et al., 2011](#); [Mueller et al., 2014](#)).

Target cells can be grown directly on the surface of a disinfected carbon-coated EM grid, typically a gold grid which is not toxic to cells. Some cells may attach directly to the carbon film support of the grid, but coatings like Poly-L-Lysine and fibronectin may be used to improve cell adherence. The cells can be infected with the virus of choice and incubated for a period of time appropriate to study the desired viral replication stages. Then, EM grids can be plunge-frozen in a cryogen (ethane or ethane/propane mixture). The thin periphery region of the cell (or filopodia, or axons) can be imaged by cryo-ET, resulting in a 3D representation of the imaged volume ([Fig. 2](#), top left panel) ([Ibircu et al., 2011](#); [Jun et al., 2013](#)).

Using cryo-ET, Riedel and colleagues were able to characterize the interaction between the viral envelope spike of Murine Leukemia Virus and the host receptor mCAT ([Riedel et al., 2017](#)). By imaging virus particles attached to the target cells and analyzing the contact extent between viral and cell membranes they were able to determine that viral attachment was in its early to intermediary stage. They also determined the average number of receptors engaged in MLV entry. Clustering of the receptors at the interface of virus and cell membrane was observed, indicating that lateral mobility of membrane proteins in the viral envelope is possible. Sub-tomogram averages of the spike show that there are large conformational changes between the pre and post fusion conformations. This is a good illustrative example of all the insights that may be derived from 3D imaging of viral processes at the cell periphery.

Cryo-ET of Cell Lamellae or Vitreous Sections

Some viral processes occur deep inside the cell, such as virus trafficking, nuclear entry, and assembly in viroplasma/viral factories. In these cases, two techniques are typically used to generate cell lamellae or sections from frozen-hydrated virus-infected cells for cryo-ET: Cryo-FIB/SEM (Focused Ion Beam/Scanning Electron Microscopy) milling and CEMOVIS.

In Cryo-FIB/SEM milling, a dual-beam system with a cryo-sample stage is used to process frozen-hydrated samples. An electron beam is used to visualize the sample and monitor the milling process. An Ion Abrasion beam is used to remove material from frozen-hydrated cells or tissues. Successive milling is made until a lamella, a thin sliver of sample typically 100–300 nm thick, is produced, which is then imaged by cryo-ET ([Fig. 2](#), bottom left panel) ([Marko et al., 2007](#)).

In CEMOVIS, a sample is cryo-fixed by HPF and is sectioned mechanically by a diamond knife in a cryo-ultramicrotome to produce thin vitreous sections (around 200 nm thick). The sections are transferred to EM grids and imaged by cryo-ET ([Al-Amoudi et al., 2004](#)). Successive sections may be imaged to increase the volume ([Fig. 2](#), bottom right panel). Nonetheless, this process is very challenging and may introduce artifacts such as knife marks and compression in the direction of the cutting ([Al-Amoudi et al., 2005](#)).

A great illustrative example of both techniques being used to study viral processes in the cellular context can be found in [Hagen et al., 2015](#) ([Hagen et al., 2015](#)). The authors used both milling and CEMOVIS to study the nuclear egress of Herpes Simplex 1. By observing viral egress in the native cellular environment, the authors were able to conclude that the nuclear egress complex (NEC) proteins were lost after the transfer of the viral capsid from the nucleus to the cytoplasm, and that the capsid proceeded to further assembly thereafter, correcting a notion born from observations of stained plastic-embedded samples. They also showed the NEC lattice organization and ultrastructure by sub-tomogram averaging and describe the mechanism by which the protein curvature drives the membrane curvature. This work is also a good example of sub-tomogram averaging of repeating NEC subunits.

Glossary

Affine extension A geometric transformation that preserves lines and parallelism (but not necessarily distances and angles).

Archimedean lattices (also known as uniform tilings) Tessellations in terms of regular polygons that have the same vertex environment throughout, i.e., the sequence and types of polygons surrounding each vertex are identical across the lattice (and are therefore used to label the lattice).

Asymmetric unit (also called: fundamental domain) The smallest unit from which a symmetric structure can be generated using the operations of the symmetry group.

Capsomers The units of capsid assembly, typically clusters of two (dimers), three (trimers), five (pentamers) or six (hexamers) capsid proteins.

Caspar-Klug theory (in short: CKT) Mathematical models of virus architecture based on the principle of quasi-equivalence, positing that capsid proteins should form the same local interactions at all positions in the capsid surface.

Gillespie-type algorithms Generate a statistically correct trajectory (possible solution) of a stochastic equation system for which the reaction rates are known.

Goldberg polyhedral Polyhedra with 12 pentagonal and otherwise hexagonal faces.

Gyrated lattice A gyrated version of the trihexagonal lattice is obtained if the edge lengths of triangular and hexagonal tiles are distinct.

Hamiltonian Paths Analysis (in short: HPA) Geometric constraints on the conformation of the packaged viral genome inside its capsid are used, in combination with bioinformatics, to identify multiple dispersed packaging signals in viral genomes.

Icosahedral Symmetry Symmetry defined by the rotational symmetries of an icosahedron, given by an ensemble of six 5-fold, ten 3-fold, and fifteen 2-fold axes.

Laves lattice Duals to Archimedean lattices, with vertices at the centers of its faces, and edges connecting vertices in neighboring faces.

Levinthal's Paradox in protein folding The conundrum of how proteins achieve their biologically functional native state swiftly via specific folding pathways, instead of a random exploration of all combinatorially possible ones. Virus assembly poses a viral equivalent to Levinthal's Paradox – how do viruses navigate the complex landscape

of combinatorially possible assembly pathways efficiently to ensure swift completion of viable capsid geometries.

Packaging signal mediated assembly An assembly mechanism reliant on the collective action of multiple dispersed packaging signals.

Packaging signal Nucleotide sequence/structure element in a viral genome that directs the packaging of the viral genome.

Polyhedron A three-dimensional shape with flat polygonal faces, straight edges and sharp corners called vertices.

Principle of genetic economy A principle introduced by Crick and Watson, arguing that viral genomes dedicate as little as possible coding capacity to viral proteins. As a consequence, viral capsids are formed from multiple copies of identical capsid proteins.

Quasi-equivalence A term used to describe protein positions in viral capsids in Caspar-Klug theory, meaning that protein positions are locally equivalent.

Traveling salesman problem The combinatorial problem of finding the shortest connected path that visits a given number of cities (nodes on a graph) precisely once before returning to the city (node) of origin.

Triangulation number series (in short: T-number series) A series of polyhedra used as models of capsid architecture in Caspar-Klug theory. The polyhedra are derived from a hexagonal lattice and are labeled in terms of the triangulation number *T*.

Triangulation Tessellations formed exclusively from triangles. The duals of the Goldberg polyhedra – triangulations called geodesic polyhedra – are used in Caspar-Klug theory as models of capsid architecture.

Trihexagonal lattice series (in short: T_t-number series) A series of polyhedra that are derived from the trihexagonal lattice and are labeled in terms of the trihexagonal number *T_t*. They provide alternative models to the surface lattices in Caspar-Klug theory, accounting also for virus architectures formed from more than one type of capsid protein, such as a combination of a major and minor capsid protein, and non-quasiequivalent capsid architectures.

Viral Capsid Protein container enclosing the genetic material of a virus.

Viral Tiling theory (in short: VTT) A mathematical theory representing viral capsids as surface tessellations called tilings. It generalizes Caspar-Klug theory and accommodates non-quasiequivalent surface architectures such as those of the polyoma- and papillomaviruses.

Introduction

Viruses package their genetic material into protein containers, called capsids, that provide protection between rounds of infection. In the vast majority of cases viral capsids adopt polyhedral shapes with icosahedral symmetry. Mathematical modeling can therefore be used to predict and classify virus architecture. Starting with an exposition of the classical Caspar Klug theory, further developments in the modeling of virus architecture are covered, that culminate in an overarching theory of icosahedral virus architecture. This theory contains Caspar Klug theory as a special case, and also covers its outliers, in particular larger and more complex viruses that are ill described by Caspar and Klug's polyhedral models. Demonstrations are given of how such mathematical models of virus architectures impact on our understanding of viral life cycles and viral evolution, and inform applications in nanotechnology.

Icosahedral capsid architecture also has implication for genome organization, mediated via multiple dispersed contacts between capsid protein and the packaged genome. Hamiltonian Paths Analysis (HPA) enables the formulation of geometric constraints on genome organization arising from these contacts. The predictive power of HPA is illustrated via its role in the discovery of capsid assembly instructions that occur in many viral genomes in the form of multiple dispersed sequence/structure motifs with affinity for capsid protein, termed packaging signals (PSs). HPA has played a major role in their discovery and characterization, and in the analysis of the PS-mediated assembly mechanism, that resulted in a paradigm shift in our understanding of virus assembly. The asymmetric organization of the viral genome inside the capsid is only one form of asymmetry in virus architecture. Other asymmetric components often occur as an integral part of the capsid shell, and such symmetry breaking in icosahedral capsids has functions that are discussed from a modeling perspective.

The Principle of Genetic Economy

A reason for the polyhedral nature of viral capsids has been given in a seminal paper by Crick and Watson. They propose that viral capsids are either helical or polyhedral due to the *principle of genetic economy* (Crick and Watson, 1956). By repeatedly synthesizing capsid protein subunits from the same genomic segment, viruses minimize the portion of their genomes dedicated to the coding of the capsid. The repeated use of the same type of capsid protein, on the other hand, results in architectures that are highly symmetrical, either helical or polyhedral.

Viral Geometry and Icosahedral Symmetry

The majority of viral capsids have polyhedral shapes, exhibiting the same rotational symmetries as an icosahedron. This means that the organization of their protein subunits in the capsid surface respects the rotational symmetry axes of icosahedral symmetry. The locations of four of these axes are indicated for the example of Satellite Tobacco Necrosis virus (STNV; PDB-id 4BCU), a small plant virus, with respect to an icosahedral reference frame in Fig. 1(a). There are in total 12 axes of 5-fold rotational symmetry through opposite vertices of the icosahedron; 20 3-fold axes through the midpoints of opposite faces; and 30 axes of 2-fold symmetry through the midpoints of opposite edges. Icosahedral symmetry implies that the capsid surface must be tessellated by 60 identical copies of the so-called asymmetric unit, or fundamental domain, of the symmetry group, that is given by the kite-shaped area indicated in green in Fig. 1(a).

If a virus capsid is formed from 60 capsid protein subunits, like STNV, then there is precisely one capsid protein per copy of the asymmetric unit, and the positions of all capsid proteins are therefore fully determined by symmetry. As the icosahedral symmetry group is the largest rotational symmetry group in three dimensions, i.e., has the largest number of elements, it guarantees the largest number of repeats of the asymmetric unit in the capsid surface. Polyhedral capsids with icosahedral symmetry therefore optimize container volume. This facilitates the packaging of the genomic cargos, which provides an explanation for the prevalence of icosahedral symmetry in virology.

Mathematical Models of Icosahedral Capsid Architecture

For viruses formed from more than 60 capsid proteins, there is more than one protein per asymmetric unit. The placement of these proteins within the asymmetric unit is not constrained by symmetry, and other geometric principles are therefore required in order to fully characterise virus architecture in these cases.

Quasi-Equivalence Theory

The first principle introduced to predict the structures of larger capsids is *quasi-equivalence* (Caspar and Klug, 1962). It posits that the identical capsid proteins forming larger capsids must make the same types of local interactions with each other in the capsid shell, that is, they must occupy similar local environments. From a mathematical point of view, this implies that their positions must conform to the organization of a lattice in terms of one type of tile, that can tessellate an icosahedral surface without gaps and overlaps. Caspar and Klug therefore modeled capsid architectures by embedding icosahedral surfaces into a hexagonal lattice (Fig. 1(b) and (c)).

Fig. 1 *Icosahedral Symmetry and Caspar-Klug theory.* (a) Four axes of icosahedral symmetry are shown superimposed on an icosahedral reference frame. The asymmetric unit of the symmetry group is a kite (green) with vertices at these symmetry axes. (b) Different options of embedding an icosahedral surface into a hexagonal grid are labeled in terms of the T -number. Triangles characterising one triangular face of this embedding are shown for the smallest options, showing the pair $(h, k) = (1, 1)$ defining the $T(1, 1) = 3$ architecture explicitly. (c) 20 identical copies of such triangles then define the icosahedral surface (shown here for the $T(2, 0) = 4$ option). (d) By identifying edges and vertices appropriately, this surface can be closed up into a 3D structure. (e) Pariacoto virus (left) and Providence virus (right) are examples of viruses organized according to the dual triangulations of such polyhedral models.

Since the icosahedral surface is formed from 20 equilateral triangles, this embedding is fully characterized once the position of one of the icosahedral edges has been fixed. Any edge connecting the midpoints of two hexagons in the lattice defines a hexagonal surface lattice with icosahedral symmetry. Characterising such edges by counting steps (denoted as h and k) between hexagonal midpoints along two vectors h and k at an angle of 60 degrees allows all possible such surface lattices to be enumerated. The example of $h = k = 1$ is shown in Fig. 1(b). The polyhedra obtained by reconstructing the 3D structures from these surface lattices (cf. Fig. 1(d)) must have 12 pentagonal faces, and $10(T-1)$ hexagonal faces, where the T -number $T = n^2 + nk + k^2$ is given in terms of the positive integers (or zero in at most one case) n and k . Such polyhedra are known as Goldberg polyhedra.

The T -number has a geometric interpretation in terms of the dual polyhedra – triangular surface lattices called geodesic polyhedra. It indicates the number of triangular faces that, by area, cover each icosahedral face, and is therefore also called the *triangulation number*. The case $T = 1$ corresponds to the icosahedron itself. Given that an icosahedron has 20 faces, the next larger and larger values describe triangulations of the icosahedral surface with $20T$ triangular faces.

Predictions and Limitations of Quasi-Equivalence Theory

Caspar and Klug interpret these polyhedral blueprints as follows: Since each triangular face has 3-fold symmetry, they assign three protein subunits within it. Therefore, the $20T$ faces accommodate precisely $60T$ capsid proteins. This implies that the protein numbers in the viral capsid models in Caspar Klug theory (CKT) are quantized. The smallest ‘allowed’ protein numbers are 60 ($T = 1$), 180 ($T = 3$), and 240 ($T = 4$). Pariacoto virus and Providence virus, shown in Fig. 1(e), exhibit such architectures; many other examples can be found on the ViPER website (Ho *et al.*, 2018), that has a function enabling the user to identify virus structures by T -numbers. The predictions of CKT were long thought to be universally true, and for over half a century, virus architectures have been classified in terms of T -numbers. However, with the development of refined imaging techniques, many outliers to quasi-equivalence theory were discovered with protein numbers violating this restriction, instigating the development of new mathematical approaches.

Viral Tiling Theory

Prominent examples of viruses with capsid protein numbers violating the Caspar and Klug rule are polyoma- and papilloma-viruses. Their capsids are formed from 360 protein subunits, that would correspond to a “disallowed” T -number of 6. The reason for this is that their capsids are formed from 72 clusters of five proteins (called pentamers), rather than the characteristic combination of 12 pentamers and otherwise clusters of six proteins (hexamers) as in Caspar and Klug’s approach. As planar lattices formed from pentagons do not exist without gaps – a result known as the crystallographic restriction – a simple adaptation of the Caspar-Klug construction is not possible in these cases. This conundrum is reminiscent of the mathematical challenges faced in the modeling of quasicrystals, alloys exhibiting long range order but lacking periodicity, that were discovered in 1984 and won Dan

Fig. 2 *Viral tiling theory.* (a) Tilings in terms of kites and rhombs explain the surface architectures of the polyoma- and papillomaviruses, shown here for SV40. (b) An adaptation of Viral Tiling theory to applications in nanotechnology reveals the structure of self-assembling protein nanoparticles used in malaria vaccine design. (c) A rhomb tiling encoding the surface architecture of bacteriophage MS2; and (d) a kite tiling for Tobacco ringspot virus.

Shechtman the Nobel Prize in Chemistry in 2011. Adapting techniques from tiling theory used in the modeling of quasicrystals, in particular Penrose tilings, a tiling approach for the modeling of virus architecture has been developed, that, among others, accounts for the surface structures of the polyoma- and papillomaviruses. The tiling for the polyoma and papilloma capsids is shown in [Fig. 2\(a\)](#), with symmetry equivalent protein subunits color-coded and organized into 72 pentamers. This is the first example ([Twarock, 2004](#)) of a theory now known as Viral Tiling theory (VTT).

In VTT, capsids are represented by icosahedral tilings formed from multiple copies of a finite set of tiles, that have a biological interpretation in terms of interactions between the protein subunits associated with that tile. These can either be interactions *between* capsomers on *within* capsomers. The kite-and-rhomb tiling in [Fig. 2\(a\)](#) is an example of the former. Here, the distinct tile types indicate different types of interactions between proteins in neighboring pentamers. In particular, interactions between pentamers occur either in groups of two (dimer interactions) or three (trimer interactions), and are represented by rhombs and kites in the tiling, respectively. As in CKT, these tiles indicate the positions of the capsid proteins. Note that, however, if tiles represent interactions between capsomers then it is not necessarily the symmetry of the tile that determines the number of proteins represented by it, but the number of edges in the tiling meeting at its vertices. For example, in the polyoma- and papillomavirus tiling, proteins are associated with those corners of a tile that correspond to a 5-coordinated vertex in the tiling.

VTT also includes the option of representing interactions within capsomers by tiles. In this case, the tile must have a footprint that represents the stoichiometry of the capsomer. Examples are shown in [Fig. 2\(c\)](#) and [\(d\)](#): a rhomb tiling representing the positions of the 90 protein dimers in bacteriophage MS2 (c); and a kite tiling representing the 3-domain architecture of Tomato ringspot virus (d). The latter is a pseudo $T = 3$ ($pT = 3$) virus formed from 60 identical copies of a protein, the three domains of which occupy the positions of a $T = 3$ polyhedral model. Note that VTT distinguishes their architectures from the $T = 3$ triangulation in CK theory, i.e., from the example shown in [Fig. 1\(e\)](#). VTT thus discriminates between different capsid layouts with the same number of capsid proteins, that would be represented by the same surface lattice in CKT.

Practical Applications

The tiling models can be used in an interdisciplinary context in order to analyze experimental data on particle assembly. An example of this is the characterization of self-assembling protein nanoparticles (SAPNs) in nanotechnology ([Indelicato et al., 2016](#)). Given information on the protein building blocks in the experiment – in this example a pair of fused helices that form contacts with other copies in groups of five (green helix) and three (blue helix) – the tiling approach enables a classification of all symmetric particle types. These can then be compared with mass spectrometry data of capsid assembly, thus identifying the likely particle morphology in an interdisciplinary context. The model applied to a protein nanoparticle used in the design of Malaria vaccines is shown in [Fig. 2\(b\)](#).

An Overarching Framework for Icosahedral Architectures

These examples beg the question whether there is a geometric principle that can be used to classify all possible icosahedral capsid geometries in virology. In order to address this, it is necessary to revisit the principle of quasi-equivalence from a biological point of view. Quasi-equivalence is based on two assumptions: (i) that capsids are formed from multiple copies of one type of protein subunit; and (ii) that these subunits form the same type of local interaction with each other. Whilst this is the case for a large

Fig. 3 An overarching design principle of viral architecture. (a) The Archimedean lattices, from left to right the hexagonal, trihexagonal, snub hexagonal and rhombihexagonal lattice, provide the basis for the construction of capsid layouts that contain the surface architectures of Caspar Klug theory as a special case. (b) The first elements of the four polyhedral series derived via an embedding of the icosahedral surface into the lattices in (a). These polyhedral series provide models for: (c) viruses formed from more than one type of capsid protein, such as Herpes Simplex Virus (right) with a trihexagonal lattice architecture (left) in which minor capsid proteins occupy the triangular lattice positions; and (d) outliers to Caspar Klug theory with protein stoichiometries disallowed by the quasi-equivalence principle, such as the 120 CP architecture of Phi6 (right), that follows a gyrated version of the trihexagonal lattice (left).

number of viruses – explaining the success of CKT – there are many examples of viruses that violate these assumptions. In particular larger and more complex viruses are often formed from more than one type of capsid protein, such as a major and minor capsid protein, thus violating (1). Such distinct types of protein subunits do not interact with each other in the same way, resulting in different types of interactions between and within protein types, violating (2). Moreover, as the example of polyoma- and papillomavirus in VTT in Fig. 2(a) demonstrates, even identical protein units do not always exhibit the same type of local interactions, and therefore cannot be expected to result in quasi-equivalent capsid architectures. This suggests that quasi-equivalence must be a special case of a more general biological principle.

Such a generalized principle of quasi-equivalence has been introduced in (Twarock and Luque, 2019a). It is based on the assumption that the local rules according to which different types of proteins (e.g., major and minor capsid proteins) interact with each other should be universal across the capsid, i.e., they assemble locally into the same type of configuration. This minimal assembly principle thus requires that different units organize into surface lattices that are formed from one type of vertex environment (one vertex type), at which a set of (potentially different) polygons meet. Each type of polygon is specific to a given type of capsid protein, and their relative sizes must reflect the footprints of the corresponding protein types in the capsid surface. For example, the areas of the polygons representing major and minor capsid proteins should correlate with their respective sizes.

Planar lattices with this property have been classified by Kepler in his *Harmonices Mundi* in 1619, and are also known as Archimedean lattices or uniform tilings. The hexagonal lattice and its dual, the triangular lattice, that are used in CKT, are special cases, and correspond to the only two examples of such lattices that are formed from a single type of polygon. Mimicking the Caspar and Klug construction for other Archimedean lattices (Fig. 3(a)), we constructed four infinite series of icosahedral polyhedra that contain the Caspar-Klug series of T -number geometries as a special case; the smallest polyhedron in each series is shown in Fig. 3(b). These polyhedra are defined by the equation $T_j(h, k) = c_j T(h, k)$, where the scaling factor c_j is related to the four lattice types in Fig. 3(a), and $T(h, k)$ is the triangulation number from CKT. In particular, c_j takes on the values: $c_h = 1$; $c_t = 4/3$; $c_s = 7/3$; and $c_r = 4/3 + 2/\sqrt{3}$ for the hexagonal, trihexagonal, snub hexagonal, and rhombihexagonal lattices, respectively; a full classification is provided in (Twarock and Luque, 2019a).

Together with their duals, the Laves lattices, these polyhedral series provide blueprints for virus architectures that also encompass the outliers of CKT and VTT, thus expanding the repertoire of allowed protein numbers in capsid architecture. A number of examples of viruses with trihexagonal lattice architectures are provided in (Twarock and Luque, 2019a), including herpes simplex virus type 1 (HSV-1) (Fig. 3(c)). HSV-1, a $T_t(4, 0) = 64/3$ architecture in the extended classification scheme, had previously been classed as a $T(4, 0) = 16$ structure in CKT. Whilst the latter correctly represents the number of major capsid

proteins (MCPs; in this case 960 VP5s) forming the hexamers and pentamers, it is at variance with their orientations in the capsid lattice. The trihexagonal lattice architecture moreover also accounts for the locations of the trimeric complexes formed from the minor capsid proteins (mCPs; here Tr1, Tr2a, and Tr2b) at the interstitial triangular lattice positions (cf. the green triangles in [Fig. 3\(c\)](#), left). Other examples presented in ([Twarock and Luque, 2019a](#)) include Halorubrum sodomense tailed virus 2 (HSTV-2), that has been classified as $T(2,1)=7$, but better agrees with a $T_t(2,1) = 28/3$ trihexagonal structure that also accounts for the gpD-like trimers occupying the interstitial trimeric positions between hexamers and pentamers. Similarly, the thermophilic bacteriophage P23-45 is better described by a $T_t(2,1) = 28/3$, rather than a $T = 7$, surface lattice due to its capsid radius, that reflects the additional surface area occupied by the triangular tiles.

Non-Quasi-Equivalent Trihexagonal Lattice Architectures

The trihexagonal (T_t) lattice geometry predicts the relative sizes of the areas occupied by MCP and mCP as 3:1, as a consequence of the size ratio of the areas covered by a hexagonal (A_H) and triangular (A_T) tile. However, in addition to the T_t lattice itself, the mathematical construction allows for a gyrated version ([Fig. 3\(d\)](#), left) in which the size of the triangles is enlarged relative to that of the hexagons. There is precisely one scaling for which A_H and A_T are such that the hexagonal and triangular positions are predicted to be occupied by the same protein subunit (i.e., the case $A_H:A_T=2$). Note, however, that this arrangement is not quasi-equivalent, as some subunits are in hexagonal and others in the triangular positions. The non-quasi-equivalent architecture of the inner capsid of Pseudomonas phage phi6 with the forbidden protein stoichiometry of 120 is an example of a gyrated $T_t(1,0)$ lattice ([Fig. 3\(d\)](#), right).

Other forms of non-quasi-equivalent architectures are higher order rhomb tilings. As Archimedean lattices have a single type of vertex environment, their duals, the Laves lattices, are formed from a single type of tile. Revisiting the generalized principle of quasi-equivalence reveals two distinct ways in which it can be realised in nature: (1) with the minimal number of protein subunits per tile (i.e., two, three, five or six proteins for rhomb, triangle, pentagonal or hexagonal tiles, respectively); or (2) with multiple identical copies of that subunit organized in a configuration that respects the symmetry of that tile. The former recovers the rhomb and kite tilings in VTT (cf. [Fig. 2\(c\)](#) and [\(d\)](#)), where each rhomb is occupied by two, and every kite by three, subunits. However, the second option presents a different way in which identical protein subunits can be arranged in a non-quasi-equivalent capsid geometry. Examples are Picobirnavirus and Zika virus ([Twarock and Luque, 2019a](#)), for which the area of each rhomb in the capsid surface is occupied by two or respectively three, dimers. These are the smallest geometries in two series of capsid architectures with $120T(h,k)$ and $180T(h,k)$ CPs, respectively. The example of Picobirnavirus is another type of pseudo $T = 2$ architecture with a CP number of 120, that is “forbidden” in the CK framework. Moreover, giant phages also present a hierarchical organization according to principle (2), but based on the gyrated lattices in [Fig. 3\(d\)](#) (left). The triangular faces (trisymmetrons) are much larger than the pentagonal ones (pentasymmetrons), and each accommodates multiple hexamers.

Implications for Viral Evolution

The importance of capsid architecture for understanding viral evolution has been pointed out by Bamford and Stuart in their visionary approach to phylogeny. They are grouping viruses into lineages based on homology of the capsid protein core folds, often combining different viral families that lack any significant sequence similarity, which is the usual measure of evolutionary relatedness. The observation in ([Twarock and Luque, 2019a](#)) that viruses with similar capsid protein folds follow the same types of capsid architectures, as exemplified for viruses using the HK97 fold, suggests that capsid geometry is indeed a good indicator for evolutionary relatedness. It also suggests that the limited spectrum of different types of capsid protein folds might be a consequence of the limited number of geometrically possible surface lattice organizations, pointing towards geometric constraints acting as drivers of convergent evolution.

A scan for a match of viral structures on the PDB-data bank with the different possible lattice types reveals that the overwhelming majority follow the hexagonal and trihexagonal lattice organizations and their duals. This could, of course, be because viruses following the other lattice types have not yet been discovered. More likely, however, this is due to deeper geometric reasons. For example, distinct lattice types imply different numbers of interfaces between capsomers, which impacts on capsid stability, as well as assembly and disassembly. Moreover, there could be a profound link with viral evolution at evolutionary timescales. It is not clear how viruses may have bridged the size gap from smaller to larger and more complex capsid structures during early stages of evolutionary history, as such transitions between different capsid structures in the CK series would correspond to significant evolutionary steps. The overarching classification scheme in ([Twarock and Luque, 2019a](#)) suggests that capsid proteins may have evolved additional domains occupying the triangular positions of a trihexagonal lattice in order to bridge those gaps. It is conceivable that this may have occurred by CPs evolving additional domains that become larger, using the geometric degree of freedom of expanding the triangular faces with respect to the pentagonal face via gyrated lattice architectures. Ultimately, or immediately, such additional domains may become independent capsid protein units in their own right. Remnants of such a mechanism are still seen, for example in the pseudo $T=3$ architectures in the family of Picornaviridae, where the polyprotein is cleaved only at a later stage in the lifecycle; or in the pseudo $T=2$ architectures exhibiting the gyrated lattice type. Note that from a mathematical point of view a gyrated version of the lattice only exists for the trihexagonal lattice. This might explain why this

Fig. 4 *Geometric constraints on genome organization in Hamiltonian Paths Analysis.* (a) A geometric constraint set derived via affine extension of the icosahedral symmetry group, encoded by a nested point array, is shown superimposed on a cross-sectional view of a cryo-EM reconstruction of bacteriophage MS2. (b) Connecting points corresponding to the binding sites of genomic RNA at neighboring capsid proteins (yellow and orange dots) results in the polyhedral shell in (c). (d) Its vertices mark potential positions of stem-loops (packaging signals, PSs) at the inner capsid shell. Connecting vertices along polyhedral edges if the corresponding PSs occur consecutively in the linear genomic sequence from the 5' to the 3' end results in a path; if the maximal number of sites are occupied, this path is called a Hamiltonian path (HP). (e) HPs are abstract book-keeping devices that do not show the exact position of the genome, which can extend into the capsid interior as shown in (e). (f) HPA has correctly predicted both the organization of the packaged MS2 genome into two hemispheres (pink and green) and the 15 PSs identified via cryo-EM.

lattice type is preferred over other Archimedean lattices, and is therefore seen as the dominant alternative to the hexagonal lattice architectures in CKT.

Virus Structure in 3D – The Hamiltonian Paths Approach

The planar surface lattices discussed above provide models for capsid organization, but ignore structural information at different radial levels. Such detail is important, however, as the structure of the inner capsid surface impacts on the conformation of the packaged genome. A mathematical approach has been developed to model 3D capsid architecture via affine extensions of the icosahedral symmetry group, resulting in a library of nested point arrays that each provides constraints on virus architecture at different radial levels (Keef, 2013). Using the outermost features of a viral capsid of interest, a best-fit point array is selected from this library. This is exemplified for bacteriophage MS2 in Fig. 4(a), where the array is shown superimposed on a cross-sectional view of the capsid and its packaged genome obtained via cryo-electron microscopy.

Note that array points map around material boundaries of the virus, and that arrays also contain points at the multiple dispersed contacts between the genomic RNA and CP, as shown as yellow and orange spheres in Fig. 4(b). Connecting such sites if they are associated with proximal CPs results in a polyhedron (Fig. 4(c)), that is a mathematical book-keeping device for the possible connections between potential genome binding sites at the inner capsid surface. However, in any given particle, each vertex can be occupied at most once. Connecting vertices along a polyhedral edge if the corresponding contact sites are consecutive in the linear genomic sequence results in a path on the polyhedron. If all vertices are occupied, this is known as a Hamiltonian path; an example of such a path is shown in yellow in Fig. 4(d). Note that if only a subset of the vertices are occupied, then the constraints are encoded by fragments of a Hamiltonian path. Such constraints on genome organization can be used, in combination with bioinformatics, to interrogate viral genomes for potential binding sites with capsid protein. This is known as the Hamiltonian Paths Approach (HPA).

Applications of the Hamiltonian Paths Approach

An Assembly Code Embedded Within the Viral Genetic Message

HPA has been instrumental in the discovery of virus assembly instructions – a “virus assembly” code – embedded within the genetic message of viral pathogens, because it provides a way of interrogating viral genomic RNAs for secondary structure elements (such as the two connected stem-loops in Fig. 4(e)) in contact with the inner capsid surface (Prevelige, 2016). Given an ensemble of candidate contact sites, typically containing more than the maximal number of possible binding sites, the Hamiltonian path provides geometric constraints that allow the identification of geometrically compatible subsets, thus narrowing down the options (Dykeman *et al.*, 2013). HPA has revealed multiple dispersed sites within the genomic RNA of bacteriophage MS2 with a

consensus sequence/structure motif recognizing CP, that we termed packaging signals (PSs) due to their roles in genome packaging and capsid assembly. Further analysis strategies have since been developed in an interdisciplinary context to identify these virus assembly instructions in a number of viruses, including major human pathogens (Twarock and Stockley, 2019b).

Note that Hamiltonian paths do not only identify PSs, but also make predictions regarding the occupancy of binding sites at the inner capsid surface. For example, the MS2 genome was predicted to be organized into two separate hemispheres (Fig. 4(f)), with one harboring more of the higher affinity sites, as was subsequently confirmed experimentally (Twarock, 2018a).

Virus Assembly Mechanisms

Hamiltonian paths also provide a means of describing the formation of viruses as a traveling salesman problem. Teaming up the geometric understanding of Hamiltonian paths with stochastic simulations of capsid assembly based on Gillespie-type algorithms has revealed fundamental insights into the mechanism of PS-mediated assembly (Twarock *et al.*, 2018b). In particular, using Hamiltonian paths as book-keeping devices for the geometries of the assembly intermediates along virus assembly pathways, it has been possible to demonstrate how PS-mediated assembly enables efficient and selective packaging of the viral genome: The cooperative action of multiple dispersed PSs, distributed along the viral genome according to a specific affinity profile, is key for selecting specific assembly pathways amongst the vast number of geometrically possible ones, and for outcompeting cellular competitor RNA in packaging (Dykeman *et al.*, 2014). PS-mediated assembly is thus essentially a solution to a viral equivalent of Levinthal's Paradox in protein folding – the conundrum of how proteins achieve their biologically functional native state swiftly via specific folding pathways, instead of a random exploration of all combinatorially possible ones. The modeling approach also demonstrates that the effects of PS-mediated assembly can only be observed at the low protein concentrations typical of a viral infection *in vivo*, but would be obscured in *in vitro* experiments in which the full CP aliquot is added at the start of the assembly reaction, as is typically the case. This need for experimental probing of the mechanism at low CP concentration, taken together with the strong variation of PSs around a sparse consensus motif, perhaps explains why the mechanism is so difficult to detect by experiment alone, and illustrates the important role of mathematical modeling in virology.

Beyond Icosahedral Symmetry

Even though the majority of viruses exhibit icosahedral symmetry, there are many other forms of structural organization. These include helical architectures, capsid shapes in the form of fullerene cones as in HIV, lemon shaped architectures among archaeal viruses, and roughly spherical shapes with a lipid membrane taken from the host cell as in influenza virus. Even many capsids classed as icosahedral have asymmetric capsid features that distort their icosahedral lattice geometry. Examples are portal proteins that are required for genome packaging into DNA viruses, or asymmetric components with a role in genome release such as the single copy of a maturation protein in MS2. It is likely that such components have multiple functions. For example, they may also play roles in nucleation of capsid assembly. Such symmetry breaking via asymmetric capsid components has implications for viral dynamics. Among others, it impacts on the pathways of capsid lattice rearrangements during maturation (Indelicato *et al.*, 2016), that occur in many viruses as a prerequisite for particles becoming infective. Apart from asymmetric capsid components, genome organization introduces asymmetry into the overall virion architecture. As capsid symmetry impacts on genome organization in viruses assembling via PS-mediated assembly, it imposes constraints that result in a certain degree of order in genome organization. As HPA demonstrates, mathematical models of capsid symmetry are therefore avenues into the characterization of such asymmetric features and their functional roles.

Conclusion

Implications of viral geometry, symmetry and symmetry breaking percolate through all aspects of virology, and are key to understanding how viruses form, evolve and infect their hosts. Geometric insights, twinned with experiment, can also act as drivers of discovery, as demonstrated by the role of HPA in the discovery of PS-mediated assembly. Modeling of viral geometry therefore has a central role in virology, revealing mechanistic insights that can be exploited in novel forms of antiviral intervention.

Glossary

Ångstrom A unit of length equal to one hundred-millionth of a centimeter to measure wavelengths and distances (1 Å = 0.1 nm).

Capsid The protein shell of a virus particle.

Capsomere The basic structural unit of a capsid which can self-assemble to form the complete capsid.

Envelope A host derived lipid membrane separating the genome from the viral capsid.

MCP Major capsid protein.

Nucleocapsid The protein capsid and the genome.

Spike Glycoprotein surface projections of varying length at regular intervals on a viral surface.

Structural proteins Proteins present in the virus particle.

Virion A virus particle capable of infecting a host cell.

VLP Virus like particle (VLP) consisting of the outer capsid without the genome.

Introduction

Viruses are nanomolecular assemblies tailored to parasitize a wide variety of hosts ranging from prokaryotes to eukaryotes. A virus particle consists of a genome, which can comprise either single- or double-stranded RNA or DNA molecule(s) protected by a protein or a proteolipid outer capsid. Viruses insert their genome into a host organism where they can replicate and assemble. They therefore have a strong influence on protein adaptation and are key drivers of molecular evolution (Enard *et al.*, 2016). Viruses occur in distinct shapes, sizes and symmetries designed for effective transmission of their genetic material. They are classified based on the type and organization of the encapsulated genome and the presence of a lipid envelope derived from the host cell surrounding the viral nucleocapsid.

Viruses occur in three predominant shapes: filaments, spheres and pleomorphic (Fig. 1). The spheres are 20-sided regular icosahedra. The size of icosahedral viruses varies from a diameter of 170 Å (porcine circovirus) to 5000 Å (mimivirus). However, pithovirus and pandoravirus, the largest known viruses, are oval and measure about 10,000 Å and 15,000 Å in size, respectively. Mimivirus, a double-stranded DNA (dsDNA) virus with a genome size of 1.2 megabase pairs has an icosahedral shape with a diameter of 5000 Å and is associated with 1200 Å-long fibers (Klose *et al.*, 2010; Raoult *et al.*, 2004; Xiao *et al.*, 2005,2009). Most plant viruses are small and are either filamentous or polygonal, as are also many bacterial viruses (Johnson and Speir, 1997; Rossmann, 2013; Solovyev and Makarov, 2016). The larger and more complex dsDNA containing bacteriophages, which infect *E. coli*, combine both filamentous and polygonal shapes (Ackermann, 1999). For example, the T4 bacteriophage is composed of an icosahedral head (1150 Å long, 210 Å in diameter) (Fokine *et al.*, 2004) with an associated 1000 Å rod-shaped long tail (Kostyuchenko *et al.*, 2005), a 460 Å-diameter baseplate and six 1450 Å-long tail fibers (Kostyuchenko *et al.*, 2003). Structures such as these are unique to bacteriophages. Animal viruses, however exhibit extreme variations in size and shape. For example, parvoviruses are icosahedrons and measure about 180–250 Å in diameter. In contrast, members of *Poxviridae* and *Togaviridae* are about 250–750 Å in diameter and are either polygons, filamentous or pleomorphic.

The viral genome encodes structural proteins, which constitute the virus particle and non-structural proteins essential for the replication of the virus inside the host cell. These proteins aid in several stages of a typical virus life cycle that includes host cell recognition, replication, assembly, maturation and the release of progeny virus particles. The capsid protects the viral genome against harsh conditions like variation in pH, temperature and degradation by enzymes during infection. The capsid also plays a role in host cell recognition and entry. Although the number and nature of the capsid building blocks vary among viruses, there are certain common principles of capsid organization that apply to most viruses.

Several excellent reviews on the principles of virus structure organization have been published over the years (Caspar and Klug, 1962; Harrison, 2007; Johnson and Speir, 1997; Klug and Caspar, 1960; Lee and Johnson, 2003; Prasad and Schmid, 2012; Rossmann, 2013; Rossmann and Johnson, 1989). Here, we give a short history of structural virology, a discussion of virus symmetry and the methods used to study virus structures followed by the current understanding of the principles of virus architecture. We will be discussing a series of example virus structures to show: (1) how virus capsid subunits are assembled, (2) what triggers their disassembly to release their genome, (3) why certain protein folds occur frequently in virus capsids, (4) how viruses recognize and enter host cells, and (5) how structures aid in the development of vaccines and anti-viral therapeutics.

General Principles of Capsid Architecture

The first significant development in structural virology was in 1935, when Stanley crystallized the infectious particles of tobacco mosaic virus (TMV) (Stanley, 1935) and subsequently Bawden and Pirie crystallized tomato bushy stunt virus (TBSV)

(Bawden and Pirie, 1938). In 1941 Bernal and Fankuchen used X-ray diffraction to establish the size and shape of TMV and TBSV particles and presented the first detailed description of any virus structure (Bernal and Fankuchen, 1941a,b). They established that the TMV virus particles consisted of a protein capsid that protected the viral genome. This work was then extended to near-atomic resolution by Franklin (Franklin, Holmes, 1958; Franklin *et al.*, 1957), Holmes (Holmes *et al.*, 1975), Stubbs (Stubbs *et al.*, 1977), and Bloomer (Bloomer *et al.*, 1978; Champness *et al.*, 1976). The description of the assembly of TMV capsid subunits around the RNA genome was among the foremost studies of virus capsid self-assembly (Butler and Klug, 1972).

In 1953, James Watson and Francis Crick reached their ground-breaking conclusion, using Franklin's X-ray diffraction images, that DNA exists in the form of a three-dimensional (3D) double helix with the two strands connected by hydrogen bonds between the nucleotides (Watson and Crick, 1953b). They also postulated the 'Central Dogma', which implied that the information flow in biological systems is from DNA to RNA to protein (Watson and Crick, 1953a). They observed that a much larger genome than observed in all known viruses would be required to code for a protein of sufficient size to completely cover the virus genome. Thus, the capsid must be constructed of multiple copies of the same protein. As each of these subunits have the same sequence and therefore the same structure, the environment of each subunit must be the same. Hence, they suggested that the capsid structure of viruses have to be regular polyhedrons. Of the five possible polyhedra, the icosahedron would have the greatest number of subunits and would, therefore, represent the most conservative way of using the least amount of genome to code for the largest possible virus (Crick and Watson, 1956; Crick and Watson, 1957). This was verified by Caspar (Caspar, 1956), who observed in an X-ray crystallographic study of TBSV that there appeared to be rotation axes at angles to each other consistent with icosahedral symmetry. The icosahedral symmetry in TBSV was also confirmed using electron microscopy (Home *et al.*, 1959; Williams and Smith, 1958).

Icosahedral Symmetry

Caspar and Klug provided the first evidence for the presence of icosahedral symmetry by analyzing the X-ray diffraction patterns of TBSV and turnip yellow mosaic virus (TYMV). An icosahedron has 12 vertices with 5-fold rotational symmetry, 20 triangular faces

Fig. 2 *Icosahedral symmetry and triangulation.* An icosahedron displayed along the 2-fold (A), 3-fold (B) and 5-fold (C) axes of symmetry. An icosahedron has twelve 5-fold axes of symmetry along each of the vertices, twenty 3-fold axes of symmetry passing through the center of triangular faces and thirty 2-fold axes through the middle of each edge. (D) The hexagonal lattice system to define triangulation (T number) of an icosahedron. The hexagonal lattice is constructed with h and k axes crossing at 60° angles. Each hexagon can be decomposed into six equilateral triangles. The coordinates on the hexagonal lattice system (h, k) are labeled. Examples of three triangles with T numbers 1, 3 and 4 are shown in green, red, and blue respectively.

with 3-fold rotational symmetry and 30 edges with 2-fold rotational symmetry (Fig. 2). This allows the placement of 60 identical subunits decorated with capsid proteins with equivalent contacts between them. However, there are many spherical viruses where the number of capsid subunits far exceed the 60 subunits required by icosahedral symmetry. To address this question, Caspar and Klug proposed an extension to Watson and Crick's strict icosahedral symmetry concept in viruses (Caspar and Klug, 1962). They suggested that capsid subunits in an icosahedron might adapt to slightly different inter-subunit interfaces and introduced the principle of quasi-equivalence for larger virus structures with more than 60 capsid subunits. They predicted a virus assembly process in which the subunits assembled into hexagonal arrays. This would give rise to a scheme where an icosahedral virus can be constructed from pentamers of triangular faces (pentons) forming the 12 vertices and hexamers of triangular faces (hexons) covering the 20 icosahedral faces. The assumption that the monomers that make a hexamer would have quasi-equivalent environments increased the number of subunits in an icosahedron from 60 to $60T$, with T representing the triangulation number.

The triangulation number (T) is the number of quasi-similar subunits per icosahedral asymmetric unit with possible values of T , because of geometric restrictions, dictated by the equation $T = h^2 + hk + k^2$. Here, h and k are the number of hexons between pentons along the h and k axes of a hexagonal array, where h and k are either zero or positive integers. To further elaborate, the formation of an icosahedron can be visualized using a uniform hexagonal lattice, where each hexagon can be decomposed into six equilateral triangles. The hexagonal lattice is constructed with h and k axes crossing at 60° angles. A pentagon can be constructed in 3D by removing one triangle from the hexagon (Figs. 2 and 3). By arbitrarily choosing one of the 5-fold vertices as the origin ($h, k = 0, 0$),

Fig. 3 The construction of an icosahedron from arrays of hexagons. $T = 3$ structure of turnip yellow mosaic virus, where (A) shows the icosahedral capsid assembly in TYMV (PDB ID: 2FZ2) and (B) the planar sheet of twenty equivalent triangles superposed on the hexagonal lattice. The $T = 3$ arrangement with $h = 1$ and $k = 1$ is indicated by a yellow arrow. (C) Schematic showing a planar sheet of 20 triangles which can then be folded up to form a closed icosahedron. Figures (A) and (B) were prepared using the Viper data base.

the positions h and k of the neighboring 5-fold vertex closest to the origin gives the T -number of that icosahedron. For example, $T = 1$ represents an icosahedron with the closest 5-fold vertex positioned at either $h = 1$ and $k = 0$ or at $h = 0$ and $k = 1$. $T = 3$, however, represents an icosahedron with the closest 5-fold vertex positioned at $h = 1$ and $k = 1$ (Fig. 3). Thus, a simple icosahedron with 60 identical subunits would have $T = 1$ symmetry. The structures of tobacco bushy stunt virus (TBSV) (Harrison *et al.*, 1978) and southern bean mosaic virus (SBMV) (Abad-Zapatero *et al.*, 1980), the first near-atomic resolution structures of icosahedral viruses, had $T = 3$ quasi-symmetries consistent with the predictions of Caspar and Klug (subsection “Non-enveloped Icosahedral RNA Viruses”). Although the amino acid sequence of the capsid proteins was rather different, both structures were very much alike with three identical protein subunits constituting the icosahedral asymmetric unit. The first animal virus structure, that of human common cold virus strain 14 (HRV14) (Erickson *et al.*, 1983; Rossmann *et al.*, 1985), mimicked the structures of TBSV and SBMV plant viruses. However, in HRV14, the three independent subunits in the icosahedral asymmetric unit were different proteins, referred to as viral proteins VP1, VP2, and VP3 (subsection “Non-enveloped Icosahedral RNA Viruses”).

Based on the equation $T = h^2 + hk + k^2$, only certain T -numbers are allowed. Therefore, the icosahedra can be further divided into three classes (Caspar and Klug, 1962; Prasad and Schmid, 2012). These classes are calculated using the formula $T = Pf^2$, where f is the largest common divisor between h and k . The first class, $P = 1$ ($T = 1, 4, 9, 16, 25, 36$ etc.), where h is greater than or equal to 1 and $k = 0$, the lattice lines run parallel to the edges of the triangular icosahedral facet. In the second class, $P = 3$ ($T = 3, 12, 27, 48, 75, 108$ etc.), the icosahedra have T numbers along the line that bisects the h and k axes with $h = k$. The third class, called the skew class, includes icosahedra with other allowed T numbers (7, 13, 19, 21, 28, 31 etc.) with the possibility of having enantiomorphic configurations. In $T = 7$ icosahedra, the asymmetric unit is made of 7 proteins giving a total of 420 capsid proteins per virus capsid. However, depending on the values of h and k , the capsid can either have a configuration of dextro (d) for $h = 1, k = 2$ or laevo (l) for $h = 2, k = 1$. For example, polyomavirus has a non-enveloped capsid with $T = 7d$ pseudo-symmetry because it is only composed of pentamers and lacks the expected hexamers in its capsid whereas Rotavirus, a non-enveloped, icosahedral virion with a double capsid structure has a $T = 13l$ symmetry for the outer capsid and $T = 1$ for the inner capsid. Another form of icosahedron, called the prolate icosahedron where the icosahedron is stretched along one axis, is found in viruses like T-even bacteriophages (Fokine *et al.*, 2004; Rao and Black, 2010). Here, the icosahedron has a central cylindrical body made of 10 triangular faces with two caps at the bottom and the top. The prolate icosahedra are characterized by the combination of a T number and an elongation number called Q according to the formula $n = 30(T + Q)$, where T is the triangulation number of the central body, Q is any positive integer and n refers to the number of subunits. The caps follow the triangulation T , whereas the main cylindrical body follows the Q number. When $T = Q$, the icosahedra becomes isometric, when $Q > T$, the icosahedron is referred to as prolate and when $Q < T$, the icosahedra is referred to as oblate.

Introduction and preparation of specimens. II. Modes of aggregation of the virus particles. III. (1) The structure of the particles and (2) biological implications. *Journal of General Physiology* 25, 111–165.

Helical Symmetry

Helical symmetry is another prevalent symmetry occurring in the capsids of numerous plant viruses, tails of bacteriophages, and flexible capsids of negative-stranded RNA genome containing viruses. Helical organization of capsids in plant viruses has the advantage that it imposes no limitations on the size of the packed RNA genome compared to icosahedral viruses which are limited by their internal volume. Helical symmetry combines rotation and translation, giving rise to a screw axis where the pitch of the helix (P) is defined as the axis rise. A helical virus structure is described by the location of subunits with respect to the helix axis, the number of subunits per helix turn (n) and the axial rise per subunit (h).

In TMV, one of the earliest and best characterized helical virus structures, the genomic RNA of 6400 bases is encapsidated by 2140 identical viral capsid proteins giving rise to a rod-like virion, 3000 Å long and 180 Å in diameter with a central hole of 20 Å in radius (Fig. 4). After the preliminary structural studies of TMV using X-ray fiber diffraction to 2.9 Å (Namba *et al.*, 1989a), a more recent cryoEM structure has been determined to a resolution of 3.3 Å (Ge and Zhou, 2011). In TMV the capsid protein subunits form a right-handed helix with a pitch of 23 Å and 16 and 1/3rd subunits in each turn. Each capsid subunit interacts with three nucleotides. The structure of the TMV genome follows the symmetry of the capsid providing details on capsid-RNA interactions and the assembly of the virus.

Methods for Studying Virus Structures

The principal techniques used to study intact virus structures are X-ray crystallography, X-ray fiber diffraction, cryo-electron microscopy (cryoEM) and cryo-electron tomography (cryo-ET). To date, according to the statistics on the VIPERdb database (Carrillo-Tripp *et al.*, 2009) about 404 virus structures have been determined using X-ray crystallography and 345 structures have been determined using cryoEM. Major accomplishments in understanding the structure of viruses were closely associated with methodological, technological and computational advances in X-ray crystallography and cryoEM and developments in molecular virology techniques.

X-ray crystallography has been the most successful technique for determining the structure of individual icosahedral viruses since the 1970s. The first of the structures determined using crystallography were of icosahedral plant viruses (Abad-Zapatero *et al.*, 1980;

Harrison *et al.*, 1978) followed by more complex animal and human viruses. X-ray fiber diffraction was used to study viruses with helical symmetry. A key issue in X-ray crystallography is the solution of the phase problem, which in the case of viruses is helped enormously by the presence of non-crystallographic symmetry (NCS). Several crystallographic milestones that have also assisted in solving many significant virus structures have been (1) the use of high intensity synchrotron radiation for automated collection of diffraction images (Rossmann, 1979,1984,1999; Rossmann *et al.*,1979); (2) determining the orientation of virions in the unit cell (Rossmann and Blow, 1962; Tong and Rossmann, 1990); (3) using non crystallographic symmetry based methods to solve the phase problem (Åkervall *et al.*, 1972; Rossmann and Blow, 1963) and the use of NCS averaging for improving the phases (Buehner *et al.*, 1974; Champness *et al.*, 1976). If, for instance, isomorphous replacement had been used to obtain a 3.5 Å structure, then averaging that structure will increase the quality of the phases of the current map which can then be used to extend the resolution of the map (usually about one reciprocal lattice point in all directions). The slightly improved map can be used again for averaging and so forth.

The above real space considerations can also be expressed in reciprocal space and by doing so give insight into why phasing can be very successful by gradual resolution increase at each stage by less than one reciprocal lattice point given knowledge of the NCS. This had been under considerable dispute until the structure of HRV14 in 1985 (Arnold and Rossmann, 1986; Rossmann *et al.*, 1985) when the initial 5 Å resolution isomorphous replacement phases were extended to a beautiful 3 Å resolution map using NCS (Rossmann *et al.*, 1992a,b).

Electron microscopy of negatively stained virus samples was among the first techniques used to recognize virus shapes and sizes (Brenner and Horne, 1959; Horne *et al.*, 1959). Subsequent development of computational techniques to reconstruct the 3D structure of viruses from 2D projection images (Crowther *et al.*, 1970) and sample freezing techniques (Adrian *et al.*, 1984; Dubochet *et al.*, 1988) to preserve the native structure, revolutionized intact virus structure determination using cryoEM (Haas and Rossmann, 1970). For the next three decades, many virus structures were determined to a resolution of 25 Å. However, the more recent development of direct electron detectors as well as other technological advances in cryoEM has made it easier and more common to obtain cryoEM electron potential maps of virus samples to a resolution better than 3 Å. Prior to this, pseudo-atomic models of the virus capsid were derived by exploiting cryoEM and X-ray crystallography-based hybrid techniques. This required high resolution structures of viral components, obtained by using X-ray crystallography to be fitted into the low resolution cryoEM capsid map of the whole virus (Kuhn *et al.*, 2002; Zhang *et al.*, 2002). CryoEM has the advantage that it can be used where crystal growth is limiting especially with heterogeneous samples of enveloped viruses and viruses in complex with antibodies, receptors or anti-viral compounds. For example, crystals of West Nile virus diffracted to about 16 Å resolution (Kaufmann *et al.*, 2010), whereas cryoEM gave a map to a resolution of 10 Å (Zhang *et al.*, 2013). In the case of pleomorphic viruses such as Rubella (Battisti *et al.*, 2012; Mangala Prasad *et al.*, 2013; 2017a), cryo-electron tomography (cryo-ET) has been the method of choice to study the 3D structure. Tomography uses a series of collected images, where the microscope stage has been tilted to give a series of 2D projections that can be combined to form a 3D image (Frank, 1992; Lucic *et al.*, 2005; Subramaniam *et al.*, 2007). However, the resolution limitation for this technique (in the absence of averaging) has been about 20 Å because of the need to reduce the dose of each image to be able to collect a 3D data set before the sample has been destroyed by repeated exposure to electrons.

Structural Folds of Capsid Proteins

One of the characteristic features of viral capsid proteins lies in the folded topology of the capsid monomers, allowing them to assemble into large, symmetrical and geometrically sophisticated architectures (Chapman and Liljas, 2003; Cheng and Brooks III, 2013). The canonical jelly-roll β -barrel, as a core structural motif, is the most common capsid fold occurring in virus shells of varying sizes (Abad-Zapatero *et al.*, 1980; Chelvanayagam *et al.*, 1992; Harrison *et al.*, 1978; Johnson and Chiu, 2000). Other common protein folds occurring in viruses are the Greek key β -barrel with six strands (Choi *et al.*, 1991a; Tong *et al.*, 1992,1993), the helix bundle (Bloomer *et al.*, 1978; Conway *et al.*, 1997; Gamble *et al.*, 1997), the immunoglobulin-like fold (Rey *et al.*, 1995) and the HK97 fold (Suhanovsky and Teschke, 2015). The structurally unique capsid proteins are also functionally unique in terms of their folding topology because of the evolutionary constraints imposed by protein-protein interactions and are most likely a consequence of geometric requirements of the building blocks to form cage-like assemblies. Here, we describe the commonly occurring virus capsid folds.

Jelly-Roll β -Barrel

Both TBSV and SBMV, the first determined icosahedral virus structures, were similar with respect to their capsid structures and organization. It was then obvious that the two virus capsid structures with no apparent sequence similarity must have diverged from a common ancestral fold, later termed as a 'jelly-roll' fold by Jane S. Richardson in 1981 (Richardson, 1981), reflecting its resemblance to a Swiss roll cake. The jelly-roll fold is also referred to as a wedge shaped fold, an RNA virus capsid β -barrel or a β -sandwich (Cheng and Brooks, 2013).

A jelly-roll fold consists of eight antiparallel β -strands that are named from B to I along the polypeptide sequence (Fig. 5). The two four-stranded sheets that form the opposite sides of a β -barrel consist of strands BIDG and CHEF, folded such that strand B packs opposite strand C, I opposite H, etc. The end strands almost form a closed barrel structure, however there is no hydrogen-bonding between the end strands of facing sheets. A single tight turn between strands E and F leads to the pairing of strands D and G, C and H, and B and I, which then roll up, Swiss cake style. Therefore, the BI and DG pairs combine to form the BIDG sheet, and

Fig. 5 *Virus capsid structure folds.* (A) and (B) show the jelly-roll β -barrel fold in satellite tobacco mosaic virus (STMV) (PDB ID: 40Q9). The β -sheets BIDG are colored green and the β -sheets CHEF are colored golden yellow. (B) The T = 1 icosahedral assembly of the subunits to form the STMV virus capsid. The icosahedral asymmetric unit is drawn as a black triangle while the 2-, 3- and 5-fold symmetry axes are drawn in red. (C) Immunoglobulin fold in the domain-III (blue) of ZIKV envelope protein E (PDB ID: 6C08). Domain I, domain II and the membrane associated helices are colored red, yellow, and gray, respectively. (D) The serine protease-like fold in the capsid of Sindbis virus (PDB ID: 1SVP) and (E) the four-helix bundle in TMV (PDB ID: 1VTM) are shown in rainbow colors (blue to red) from N- to C-terminus. (F) The HK97 coat protein in the immature state (PDB ID: 3E8K). The common secondary structural elements observed in HK97 fold are labeled.

the CH and EF pairs combine to form the CHEF sheet. However, variations to the common core might occur in different viruses. There may be one or two additional strands like the β -strand A in TBSV outside the capsid's common fold. The length of the strands might also differ depending on triangulation number and capsid architecture. The largest variations occur in the size of the loops connecting the β -strands. In some viruses, these external loops come together to form antigenic sites (Rossmann *et al.*, 1985) and in others the loops account for the increase in capsid size (McKenna *et al.*, 1992a,b). Most of the jelly-roll folds are about 180 amino acids and can be as big as 580 amino acids in parvoviruses (Tsao *et al.*, 1991).

A large number of viruses build their capsids using either single or double jelly-roll fold capsid subunits. Double jelly-roll proteins have presumably evolved from single jelly-roll proteins by gene duplication. Single jelly-roll capsid folds are found primarily in many icosahedral RNA and DNA viruses. However, the majority are positive-sense single-stranded RNA viruses and the only dsDNA virus with single jelly-roll folds are the members of *Papillomaviridae* and *Polyomaviridae*. The double jelly-roll capsid proteins are found exclusively in dsDNA viruses spanning a large capsid size range. Most members of the double jelly-roll fold group are icosahedral, a few families such as *Poxviridae* and *Ascoviridae* have oval or brick-shaped mature virions.

The Immunoglobulin-like Fold

The immunoglobulin fold is found in a vast variety of proteins of different functions such as antibodies, cellular adhesion molecules, the receptor tyrosine kinase and many other molecules. The canonical immunoglobulin fold consists of a 7-stranded antiparallel β -sheet sandwich within which there is extensive hydrogen bonding. One example in a virus is one of the domains of a flavivirus envelope glycoprotein (E) (Rey *et al.*, 1995). The flavivirus protein E consists of three domains: The N-terminal domain-I, which is an antiparallel β -barrel quite different from the jelly-roll fold, a β -sheet rich domain-II and the C-terminal domain-III with an immunoglobulin fold. In flavivirus E protein domain-III, the three- (β -sheet CFG) and four- (β -sheet ABED) member sheets face each other and are commonly linked by a disulfide bond. The domain topology resembles a Greek key (Fig. 5).

The Serine Protease Fold

The serine protease fold is observed in chymotrypsin, many other proteases and viral proteins. It is again an anti-parallel Greek key β -barrel with six-strands. Examples of viruses with this domain as core protein can be found in the capsid proteins of the members of *Togaviridae* such as Chikungunya virus (CHIKV) (Sun *et al.*, 2013b), Sindbis virus (Choi *et al.*, 1991a), Ross River virus, Rubella (Mangala Prasad *et al.*, 2013) and Eastern equine encephalitis virus (Hasan *et al.*, 2018b) (Fig. 5). In Sindbis virus, the capsid polypeptide is folded into two similar 'Greek key' β -barrel domains with the substrate site situated between the domains. The capsid structure of Sindbis virus identified Ser215, His141 and Asp163 as the essential catalytic triad as in other serine proteases (Choi *et al.*, 1991a).

The Four-helix Bundle

The four-helix bundle is a common motif in which antiparallel α -helices are packed side by side with a close packed hydrophobic core (Fig. 5). It is also found in a wide range of proteins with diverse functions like ferritin, various cytochromes, cytokines, growth hormones etc. Viral examples include the coat protein of TMV, capsid of hepatitis B and the C-terminal domain of the HIV-1 capsid (Bloomer *et al.*, 1978; Conway *et al.*, 1997; Gamble *et al.*, 1997). Each capsid subunit of TMV consists of 158 amino acids assembled into a four-helix bundle, which are joined by a loop proximal to the virion axis. Each coat protein interacts with 3 RNA nucleotides (Namba *et al.*, 1989b).

The HK97 Fold

HK97 capsid fold is termed after the first capsid protein structure solved by X-ray crystallography of bacteriophage HK97 (Helgstrand *et al.*, 2003; Suhanovsky and Teschke, 2015; Wikoff *et al.*, 2000). Most of the viral capsids using the HK97-fold are found in bacteriophages. Additionally, this fold is also found in the capsids of Herpes Simplex virus type 1, murine cytomegalovirus, pseudorabies virus and the rhesus monkey rhadinovirus. Viruses using the HK97-fold share unexpected similarities beyond the fold of their coat proteins including the architecture of their virions, an internal scaffolding protein-mediated assembly, active dsDNA packaging, and capsid maturation events (Suhanovsky and Teschke, 2015).

The HK-97 fold is characterized by having an N-arm (sometimes α -helical rich), an E-loop with variable lengths that is a two-stranded anti-parallel β -sheet (β 2 and β 3), a peripheral P-domain with a long helix called the "spine helix" and an unusually long β -sheet; and an A-domain (axial domain) with a central β -sheet referred to as the β -hinge surrounded by short helices and loops (Fig. 5).

Fig. 6 $T = 3$ icosahedral capsid structure of non-enveloped RNA viruses. (A) The capsid structure of tomato bushy stunt virus (TBSV) (PDB ID: 2TBV). (C) A surface representation of human rhinovirus 14 (HRV14) (PDB ID: 4RHV). The icosahedral asymmetric unit of TBSV (B) consists of three similar subunits colored in red, blue and green, whereas in HRV14 (D) the subunits are formed by different proteins and labeled as VP1 (blue), VP2 (red), VP3 (red), and VP4 (yellow).

Capsid Assembly

Non-Enveloped Icosahedral RNA Viruses

The first icosahedral RNA plant virus structures, TBSV (Harrison *et al.*, 1978; Winkler *et al.*, 1977) and SBMV (Abad-Zapatero *et al.*, 1981), had similar capsid folds (jelly-roll fold) and organization with three independent subunits (A, B, and C) in the icosahedral asymmetric unit arranged around a quasi-3-fold axis (as predicted by Caspar and Klug). These structures clearly established that virus capsids with more than 60 subunits were organized based on a triangulated icosahedral lattice as described by Caspar and Klug (Caspar and Klug, 1962). The capsid is composed of 180 capsid subunits and exhibited a $T = 3$ capsid organization with rings of pentons and hexons. The assembly of these viruses occurred via AB and CC dimers. However, the AB dimer had a disordered amino-terminal β -strand compared to the one of the CC dimer, which was ordered, giving the two types of dimers a different curvature on the virus surface (Fig. 6).

The first animal virus structure was that of HRV14 (Arnold *et al.*, 1987; Erickson *et al.*, 1983), which mimicked the structures of TBSV and SBMV plant viruses. HRV14 belongs to the family of picornaviruses, which are small icosahedral animal viruses of about 300 Å diameter with a positive-sense eight thousand base RNA genome. However, while in the plant viruses the three protein

subunits in the icosahedral asymmetric unit were identical, the icosahedral asymmetric unit of HRV14 was composed of three independent subunits of the viral proteins: VP1, VP2, and VP3 (and VP4 which is internal in the mature virus) (Fig. 6). The capsid is composed of 60 copies of VP1, VP2, and VP3 (and internal VP4) arranged with pseudo $T = 3$ icosahedral symmetry. Nevertheless, each subunit had the same fold referred to as the “jelly-roll” fold. Shortly after the determination of the HRV14 structure and its extraordinary evolutionary implication, Hogle was able to determine the structure of poliovirus serotype 1, using the same phase extension technique as had been pioneered for HRV14 (Hogle *et al.*, 1985). This further confirmed the remarkable similarity of simple plant and animal RNA viruses.

The structure determination of HRV14 was not only a significant advancement in the method used for the analysis of X-ray diffraction data but was also informative of the functions required by the virus for infecting a cell and for replication. Viral escape mutations for a series of neutralizing monoclonal antibodies were all found to be on the virus surface and thus were likely the site of antibody binding (Sherry *et al.*, 1986; Sherry and Rueckert, 1985). The surface of HRV14 had a deep depression (“canyon”) around each pentameric vertex (Rossmann *et al.*, 1985). None of the MAb binding sites were in the canyon. This, therefore, suggested that the canyon might be the site where cellular receptor molecules could bind without experiencing any inhibiting viral mutations (Rossmann *et al.*, 1985; Rossmann and Palmenberg, 1988). Thus, by hiding the receptor binding site in the canyon (which would require a long thin receptor molecule), the virus could evade the host’s immune system while still being able to bind to the same receptor molecule (Rossmann, 1989). Subsequently it was established that most HRVs use intercellular adhesion molecule 1 (ICAM1) as receptor (Greve *et al.*, 1989; Staunton *et al.*, 1989). In one of the earlier applications of cryoEM, Rossmann and colleagues verified that indeed ICAM1 bound into the canyon as predicted (Olson *et al.*, 1993).

Another significant discovery related to the structure of HRV14 was that a series of anti-rhino-viral compounds bound into a hydrophobic pocket within VP1 (Smith *et al.*, 1986). This pocket was below and close to the canyon. It was shown that binding one of the antiviral compounds being developed by the Sterling Winthrop Company caused an enlargement of the pocket and a change of structure in the canyon, explaining why the binding of these compounds inhibited cellular attachment. Furthermore, it was found that this pocket was occupied by a small stabilizing lipid in HRVs and poliovirus. Thus, binding of the infectious virus to ICAM1 would displace the stabilizing “pocket factor” and prepare the virus for the release of its genome into the cytoplasm of the cell containing the ICAM1 (Filman *et al.*, 1989; Oliveira *et al.*, 1993; Rossmann, 1994; Smyth *et al.*, 1995). These results stimulated extensive work by the ViroPharma Company to create an inhibitor that was effective over a wide range of HRV serotypes, resulting in the development of “Pleconaril” (Hayden *et al.*, 2003; Xiao *et al.*, 2011). Although this compound was successful in clinical trials it put women on contraceptive hormones at risk of conception. Thus, the drug never reached the pharmaceutical market.

Enveloped Icosahedral RNA Viruses

Many major viral pathogens such as human immunodeficiency virus (HIV), hepatitis B virus (HBV), influenza viruses, herpes simplex virus (HSV), coronaviruses as well as various poxviruses, alphaviruses and flaviviruses contain host-derived lipid membranes studded with glycoproteins. Among these, members of *Hepadnaviridae* (ex: HBV) and *Herpesviridae* have an internal icosahedral capsid shell surrounded by an amorphous tegument and a lipid envelope embedded with glycoproteins. Flaviviruses and alphaviruses, however, have an icosahedral outer shell and an internal lipid membrane separating the outer glycoprotein shell from the genome (Mukhopadhyay *et al.*, 2005).

Alphaviruses have a positive-sense ssRNA genome that is about 11 kb in length and codes for 9 proteins (Kuhn, 2007). The 3' end of the genome is transcribed for subsequent translation into a polyprotein precursor containing the three structural proteins PE2 (the precursor of E3 and E2), E1, and the capsid protein. The structures of a number of alphaviruses have been determined using cryoEM to resolutions better than 10 Å, including the structure of Chikungunya virus-like particles to 5.3 Å resolution (Sun *et al.*, 2013b), Venezuelan equine encephalitis virus to 4.6 Å resolution (Zhang *et al.*, 2011a), Eastern equine encephalitis virus to 4.4 Å resolution (Hasan *et al.*, 2018b) and Sindbis virus to 3.5 Å resolution (Chen *et al.*, 2018). Alphaviruses have an external diameter of about 700 Å and are icosahedral with quasi- $T = 4$ symmetry (Fuller, 1987; von Bonsdorff and Harrison, 1975; von Bonsdorff and Harrison, 1978). They have a nucleocapsid core that is completely surrounded by a lipid envelope, derived from a host membrane, into which is embedded an icosahedral array of glycoproteins. A single virus particle contains 240 copies each of the E1 and E2 glycoproteins in the mature virus (in addition 240 copies of E3 in the immature virus) that form 20 “i3” spikes situated on the icosahedral 3-fold axes and 60 quasi-3-fold “q3” spikes at general positions (Cheng *et al.*, 1995; Zhang *et al.*, 2002). There are 240 copies of the capsid protein on the internal cytoplasmic side of the viral lipid membrane, arranged as 12 pentamers about the 5-fold vertices and 30 hexamers about the icosahedral 2-fold vertices, consistent with the $T = 4$ symmetry of the glycoprotein on the external side of the membrane. The capsid protein of alphaviruses is similar to trypsin-like proteases and participates in the assembly process (Choi *et al.*, 1991b) (Fig. 7).

The E1 glycoprotein of CHIKV forms three β -barrel domains (I, II, and III). The CHIKV E2 glycoprotein is arranged into three immunoglobulin-like domains A, B and C (Gibbons and Kielian, 2002; Li *et al.*, 2010; Voss *et al.*, 2010). Domain A contains the receptor binding site, domain B is at the distal end of each spike protecting the fusion loop on DII of E1 and domain C is situated closest to the viral membrane. The E1 glycoprotein contains a hydrophobic fusion loop that is responsible for membrane fusion with an endosomal membrane when initiating infection. The E2 protein can bind to cellular receptors and protects the E1 fusion loop at neutral pH. During the initial stages of infection, the host cellular receptor is recognized by the surface glycoprotein E2.

Fig. 7 $T = 4$ icosahedral capsid architecture in immature Chikungunya virus (CHIKV). (A) Electron potential map of immature CHIKV viewed down an icosahedral 2-fold axis. The icosahedral asymmetric unit is drawn as a black triangle and 2-, 3- and 5-fold symmetry elements are represented as oval, triangle and pentagon, respectively. The four subunits of icosahedral asymmetric units are labeled from 1 to 4 in white text. (B) Internal capsid shell of immature CHIKV. (C) Central cross-section of (A) with the represented components colored as labeled. (D) The fitting of E1-E2-E3 and C coordinates into the region outlined in (C). Figure adapted from Yap, M.L., Klose, T., Urakami, A., *et al.*, 2017. Structural studies of Chikungunya virus maturation. *Proceedings of the National Academy of Sciences of the United States of America* 114, 13703–13707.

Once the virus has been internalized, the low pH of the endosome causes the virion to undergo an irreversible conformational change resulting in the disassociation of E2 from E1 and the formation of E1 trimers. Upon E2 disassociation, the fusion loop then binds to and fuses with the endosomal membrane. Finally, the viral genome is released into the host cytoplasm, where replication of new viral particles can begin (Kielian and Rey, 2006; Lescar *et al.*, 2001; Lu *et al.*, 1999; Marsh and Helenius, 1989).

The presence of the lipid causes some heterogeneity, making it often difficult to crystallize these viruses (Harrison *et al.*, 1992). Instead the structure of many of these larger, lipid containing viruses have been determined by using cryoEM to provide a lower resolution structure of the virus and higher resolution X-ray crystal structures of the components. The latter could then be fitted into the EM structure of the whole virus. A particularly good early example was the determination of the mature dengue virus structure (Kuhn *et al.*, 2002). However, more recently it has been possible to determine the structure of lipid containing viruses to about 3 Å resolution with the development of direct electron counting detectors for electron microscopes and general

Fig. 8 $T = 3$ icosahedral capsid architecture in flaviviruses. (A) ZIKV capsid formed by herringbone pattern of 6 E-M heterodimers. The E proteins are shown as $C\alpha$ backbone and the icosahedral asymmetric unit is outlined by a black triangle. The E protein domains E-DI, E-DII, E-DIII and the fusion loop are colored in red, yellow, blue and green, respectively. (B) E-M heterodimer with labeled secondary structure elements. The stem and transmembrane helices (E-H1-3, E-T1-T2) of the E protein and the M protein (M-H1-3) are colored in light blue and light brown, respectively. Residue numbering and domain definitions are shown as a linear peptide. Figure adapted from Sevvana, M., Long, F., Miller, A.S., et al., 2018. Refinement and analysis of the mature Zika virus cryo-EM structure at 3.1 Å resolution. Structure 26, 1169–1177.

improvements to microscopes and techniques. For instance, the structure of mature Zika virus (ZIKV) was determined to about 3 Å resolution using cryoEM (Sevvana et al., 2018), thus also confirming the earlier hybrid techniques.

Similar to other flaviviruses, ZIKV is an enveloped, single-stranded, positive-sense RNA virus (Hasan et al., 2018a; Sevvana et al., 2018; Sirohi et al., 2016). The 11 kb RNA genome is translated into a long polyprotein. It is post-translationally cleaved by host and viral proteases into three structural proteins: pre-membrane (prM), envelope (E), and the capsid (C) as well as seven non-structural proteins (Sirohi and Kuhn, 2017). The E and prM proteins form a protective capsid around the genome. The E-protein mediates the assembly of virus, virus entry and fusion with host membrane and contains putative receptor binding sites. It forms a complex with prM in the endoplasmic reticulum shortly after its synthesis. The E-prM complex is arranged as 60 trimeric spikes ($T = 3$) on the surface of the immature virus (Mangala Prasad et al., 2017b). The pr domain of prM prevents premature fusion to membranes during virus production. Immature virions undergo pH-induced conformational changes to form the mature virion. Mature virus particles are formed after the pr domain is cleaved from the prM protein by furin in the trans-Golgi network. The icosahedral mature ZIKV consists of 180 copies of E and M proteins arranged in 60 asymmetric units (quasi- $T = 3$). Each icosahedral asymmetric unit consists of three E-M oligomers. Three parallel dimers from adjacent asymmetric units form a “raft”. Therefore, there are 30 rafts arranged in a herringbone pattern on the surface of the mature virus (Fig. 8). Flavivirus membrane fusion is initiated by E-protein interaction with a potential receptor molecule and the endocytosis of the virus. This is followed by low pH-induced conformational changes in the endosome, exposure of the fusion loop and its interaction with the endosomal membrane. The E-proteins then rearrange into trimeric structures (fusogenic trimer) leading to the fusion of viral and endosomal membrane and subsequent release of viral genome into the host cytosol.

Though, most of the flavivirus structures have icosahedral symmetry, a recent study has shown that immature Kunjin and Zika viruses are not accurately icosahedral (Therkelsen et al., 2019). Their nucleocapsid core approaches close to one side of the external glycoprotein shell, indicating the presence of a special, unique region that may have been created while interacting with glycoproteins to promote budding from the endoplasmic reticulum (ER) in infected cells and may be required for genome packaging in flaviviruses. Furthermore, on the opposite face on the exterior glycoprotein surface, there is a departure from exact icosahedral symmetry that may reflect the final step in budding. Similar asymmetric properties may have been overlooked in the usual averaging procedures assumed in the study of most essentially icosahedral viruses.

Small Icosahedral ssDNA Viruses

Two examples of small icosahedral ssDNA viruses are ΦX174 (McKenna et al., 1992b), which belongs to the *Microviridae* family, with a single-stranded circular DNA and parvoviruses with a linear genome. Parvoviruses have a 5000 nucleotide ssDNA genome, and typically have a $T = 1$ icosahedral capsid that is about 260 Å in diameter (Fig. 9). Most mammalian parvoviruses have 60 subunits of VP1, VP2, and VP3 in the viral capsid. Many parvovirus structures such as human B19 virus-like particles, canine parvovirus, feline parvovirus, porcine VLP's and murine VLP's were determined to near atomic resolution using X-ray crystallography (Agbandje et al., 1993; Kaufmann et al., 2005; 2008; 2004; Simpson et al., 2000; Simpson et al., 2002; Tsao et al., 1991;

Fig. 9 Structure of icosahedral ($T = 1$), human parvovirus B19 VP2 particles. (A) Surface topography of B19 color-coded according to the ribbon diagram in (B). (B) Secondary structure of parvovirus B19 VP2 showing the jelly-roll β -barrel fold. The surface loops connecting the strands of the β -barrel are colored as follows: dark blue, BC loop; dark green, DE loop; light blue, EF loop; red, GH loop; light green, HI loop; yellow, C-terminal amino acids. Figure adapted from Kaufmann, B., Simpson, A.A., Rossmann, M.G., 2004. The structure of human parvovirus B19. *Proceedings of the National Academy of Sciences of the United States of America* 101, 11628–11633.

Wu and Rossmann, 1993; Xie and Chapman, 1996). Adeno-associated parvoviruses (AAV-2) are of particular interest because of their potential use in gene therapies (DiMattia *et al.*, 2012; Hueffer *et al.*, 2003b; Lerch *et al.*, 2012; Padron *et al.*, 2005; Walters *et al.*, 2004; Xie *et al.*, 2002). The capsid proteins of parvoviruses have large insertions on their jelly-roll structure. These account for most of the, interactions between neighboring subunits as well as receptor interactions (Chapman and Rossmann, 1996; Tsao *et al.*, 1992). For example, canine and murine parvoviruses can use transferrin (TfR) receptor for binding and infection (Hueffer *et al.*, 2003a). However, the TfR molecule only binds to a few of the 60 available binding sites on the virus thereby inducing asymmetry in the icosahedral virus (Hafenstein *et al.*, 2007).

Bacteriophage Φ X174 is a tailless phage that contains a single-stranded, closed and circular DNA with about 5000 nucleotides (Dokland *et al.*, 1999; 1998; McKenna *et al.*, 1992b). The $T = 1$ mature icosahedral virus consists of four structural proteins, J, F, G, and H. The capsid of 260 Å diameter is formed by 60 F subunits. The 12 pentameric spikes formed by 60 copies of the G protein rise about 30 Å above the capsid surface and both F and G subunits have jelly-roll folds. There are 12 copies of the H protein, which form a tail tube similar to the tail tube of the common tailed dsDNA phage during infection for the insertion of DNA into the host cell (Sun *et al.*, 2013a). Structural studies shed light on the assembly of Φ X174, which proceeds via virally encoded scaffolding proteins (B and D) both of which are discarded when assembly is complete (Fig. 10).

Large Icosahedral dsDNA Viruses

Nucleocytoplasmic large dsDNA viruses (NCDLVs) infecting a wide variety of organisms' span members of the *Asfaviiridae*, *Ascoviridae*, *Marseilleviridae*, *Mimiviridae*, *Pandoraviridae*, *Phycodnaviridae*, *Iridoviridae*, and *Poxviridae*. Most NCDLVs are roughly icosahedral in shape. However, members of Poxviruses, Ascoviruses, and Pandoraviruses are pleomorphic. CryoEM reconstructions of several icosahedral NCDLVs infer similar capsid organization with large T numbers (Andreani *et al.*, 2017; Cherrier *et al.*, 2009; Klose *et al.*, 2016; Okamoto *et al.*, 2018; Reteno *et al.*, 2015; Xiao *et al.*, 2017; Yan *et al.*, 2005; 2000; 2009; Zhang *et al.*, 2011b). An inner membrane that separates the genome from the external capsid is observed in most NCDLVs except Faustoviruses, which have an internal capsid.

The capsomeres in icosahedral NCDLVs are arranged in trisymmetrons (20 triangular arrays) and pentasymmetrons (12 pentagonal arrays) (Fig. 11) (Klose and Rossmann, 2014). The capsid is assembled from pseudo-hexagonal, closely arranged trimeric capsomeres where each subunit is formed by a double jelly-roll fold protein. Each capsomere has a diameter of about 75–85 Å and a height of 75 Å. Because of their size range, the capsomeres can have two orientations related by a six-fold rotation. First, the capsomeres within each trisymmetron can have the same orientation or, second, they can be rotated by 60° relative to neighboring capsomeres which creates cleavage planes between neighboring trisymmetrons (Wrigley, 1969). The five-fold vertices are formed by a pentameric single jelly-roll fold protein. The pentasymmetrons have a constant size and consist of 30 trimeric double jelly-roll capsomeres and one pentameric single jelly-roll protein. It was postulated that this constant size is ideal to relieve the strain induced around the five-fold axis for icosahedral NCDLVs with large diameters.

Another characteristic feature of NCDLVs is the presence of minor capsid proteins found underneath the major capsid proteins towards the inside of the virus capsid as can be seen in high resolution structures of faustovirus (Klose *et al.*, 2016), Chilo iridescent virus (CIV) and Paramecium bursaria chlorella virus 1 (PBCV-1) (Zhang *et al.*, 2011b). The minor capsid proteins

Fig. 10 Capsid assembly pathway in *Microviridae*. The first intermediates are formed by pentameric assemblies of F capsid in 9 s and G spike proteins in 6 s particles. With the help of internal and external scaffolding proteins (B, D, and H), these are later assembled into an empty protein capsid shell called the procapsid. The ssDNA is concurrently synthesized and packaged into the procapsid in complex with DNA-binding protein J, therefore forming the mature virion. Figure adapted from Bernal, R.A., Hafenstein, S., Olson, N.H., *et al.*, 2003. Structural studies of bacteriophage ϕ 3 assembly. *Journal of Molecular Biology* 325, 11–24.

support the outer capsid shell, connect the neighboring trisymmetrons and/or connect the outer capsid to the inner membrane. Some NCLDV s like mimivirus (Xiao *et al.*, 2005,2009; Klose *et al.*, 2010) and PBCV-1 also have a unique vertex where the membrane becomes separated from the capsid. Many NCLDV s have decoration proteins and surface fibers attached to the viral capsid. Mimivirus is covered by a dense layer of surface fibers except near the unique vertex called the stargate, which is tightly associated with the adjacent capsomers.

One of the most studied NCLDV s is PBCV-1, where a recent near-atomic resolution structure identified several of the minor capsid proteins and cast light on the capsid assembly pathway (Fang *et al.*, 2019). PBCV-1 has a 330 kbp genome that encodes 416 proteins, of which 149 different proteins were identified in the mature virion. The nucleocapsid is surrounded by a membrane, which in turn is surrounded by a roughly icosahedral capsid shell giving it an overall size of 190 nm. It also has a unique vertex with a spike structure required for host entry. The outer shell consists of the MCP (Vp54) and the penton protein P1. Each tri- and pentasymmetron contains 66 (MCP) and 31 (30 MCP + 1 P1) capsid proteins respectively, arranged in an icosahedral lattice with a triangulation number of $T = 169d$. The high resolution cryoEM structure led to the identification of the penton protein, P1, and 13 minor capsid proteins (named P2 through P14). The minor capsid proteins form a hexagonal network below the outer capsid shell. Most of the minor capsid proteins are primarily located at the interface between neighboring capsomeres. The size of the viral capsid is determined by a tape-measure protein, P2, and the zip protein P11 which plays a crucial role in cementing neighboring symmetrons (Fig. 11).

Faustovirus, on the other hand uses two concentric capsid shells to protect its genome (Klose *et al.*, 2016). Consequently, two distinct types of particles were observed in cryoEM images of purified virus. The larger icosahedral particle constituting the outer and inner capsids measured about 2600 Å in diameter, whereas the smaller particles with only an inner capsid measured between 1600–1900 Å. The capsomere on the outer capsid is arranged with a triangulation number of $T = 277$ ($h = 7$ and $k = 12$). The

(C) $T = 277$ and $T = 64$ capsid organizations of faustovirus external and internal capsid shells respectively. (D) CryoEM map of the overall structure of the PBCV-1 capsid. The boundaries of neighboring trisymmetrons and pentasymmetrons are outlined in black. (E) The cryoEM density of the minor capsid proteins and the penton proteins after subtracting the density for MCP. Each protein is depicted in a different color as indicated to the right of the image. The h and k indices are labeled on the icosahedron in panels (C) and (D). The radial color gradient scale bar is in Å. Figures adapted from: (A), (B), and (C) Klose, T., Reteno, D.G., Benamar, S., *et al.*, 2016. Structure of faustovirus, a large dsDNA virus. *Proceedings of the National Academy of Sciences of the United States of America* 113, 6206–6211. (D) and (E) Fang, Q.L., Zhu, D.J., Agarkova, I., *et al.*, 2019. Near-atomic structure of a giant virus. *Nature Communications* 10, 388.

icosahedral asymmetric unit is composed of one penton protein and 276 MCPs. Each tri- and pentasymmetron of the outer capsid shell contains 360 (MCP) and 31 (30 MCP + 1 P1) proteins, respectively (Fig. 11).

Tailed Bacteriophages

The structure of dsDNA bacteriophages is unique in that most of them have tails attached to a special pentameric vertex of their capsids (Fokine and Rossmann, 2014). The unique vertex in most bacteriophages is occupied by a dodecameric portal protein, which forms a channel for genome packaging during virion assembly and subsequent exit during infection. Tailed bacteriophages belong to the order *Caudovirales*, which are further divided into three families: *Myoviridae* (i.e., T4 and ϕ 92 have long, straight contractile tails), *Siphoviridae* (i.e., lambda and HK97) have long flexible non-contractile tails, and *Podoviridae* (i.e., T7) have short non-contractile tails.

Capsid heads of tailed bacteriophages come in a large variety of sizes and range in diameter from about 400–1700 Å with either icosahedral or prolate heads. The capsid contains linear double-stranded DNA packaged to a high density of about 500 g/l and exerts an internal pressure of tens of atmospheres on the capsid walls. The capsid precursor, called the procapsid or prohead, is assembled at the portal vertex by copolymerization of the MCP and scaffolding proteins. The scaffolding protein regulates the correct geometry of the capsid. The prohead consists of the portal protein, the outer MCP, the internal scaffolding protein and in some cases other minor capsid proteins. The scaffolding protein and the internal core are degraded in the procapsids of many phages by head maturation proteases, therefore making space for DNA packaging. The genome is packaged by a DNA translocation motor via the portal vertex and is ATP-dependent. DNA packaging is followed by large structural rearrangements, an increase in internal volume and attachment of other proteins (for example decoration proteins) to form the mature capsid. After DNA packaging, the DNA translocation motor is removed and the capsid assembly is completed by sealing the portal gate, the

Fig. 12 Structure of T4 bacteriophage ($T = 13$ laevo, $Q = 20$, $h_1 = 3$, $k_1 = 1$, $h_2 = 4$, and $k_2 = 2$). (A) CryoEM reconstruction of the T4 capsid and extended tail. The capsid, tail sheath, phage collar and whiskers are colored cyan, green, blue and gold respectively. The density corresponding to the baseplate and long tail fibers is colored magenta. (B) Schematic representation of the bacteriophage T4 neck and tail components. (C) CryoEM reconstruction of the T4 head viewed perpendicular to the 5-fold axis. The capsid proteins, gp23 and gp24, are shown in blue and magenta respectively, *soc* is in white, *hoc* is in yellow, and the tail is in green. The facet triangle is shown in blue and the basic triangles in black. Adapted from: (A) Fokine, A., Zhang, Z., Kanamaru, S., *et al.*, 2013. The molecular architecture of the bacteriophage T4 neck. *Journal of Molecular Biology* 425, 1731–1744. (B) Fokine, A., Rossmann, M.G., 2014. Molecular architecture of tailed double-stranded DNA phages. *Bacteriophage* 4, e28281. (C) Fokine, A., Chipman, P.R., Leiman, P.G., *et al.*, 2004. Molecular architecture of the prolate head of bacteriophage T4. *Proceedings of the National Academy of Sciences of the United States of America* 101, 6003–6008.

attachment of head completion proteins and the assembly of the tail. Bacteriophage tails are designed to recognize host cells, penetrate the cell envelope and deliver the genome. Their length varies from ~ 100 Å in *Podoviridae* to ~ 8000 Å in some *Siphoviridae*. Most tails of the members of *Myoviridae* and *Siphoviridae* consist of a tail tip complex for host cell recognition, a tail tube, which makes a conduit for genomic DNA with a contractile sheath around it in some phages and the terminator proteins near the tail-head interface (Fig. 12).

One of the most studied bacteriophage structures is of T4 bacteriophage, which infects *E. coli*. The dsDNA genome encodes about 40 structural proteins. The mature virus consists of an 1150 Å-long and 850 Å-wide prolate head encapsidating the genomic DNA. The head is attached to a 1000 Å-long and 210 Å-diameter cylindrical contractile tail and is terminated with a 460 Å-diameter baseplate (Fokine *et al.*, 2004; Kostyuchenko *et al.*, 2003) (Fig. 12). The baseplate is associated with six 1450 Å-long fibers (Aksyuk *et al.*, 2009; Kostyuchenko *et al.*, 2005). The distal ends of the long tail fibers (made of gp37) recognize the host cell (Bartual *et al.*, 2010) and then transfer the signal to the baseplate to unfold the short tail fibers (gp12) (Thomassen *et al.*, 2003; van Raaij *et al.*, 2001). The short tail fibers subsequently bind to the lipopolysaccharides on the surface of the *E. coli* host. The unfolding of the short tail fibers results in large conformational changes of the dome-shaped baseplate to a star-shape as the tail sheath (gp18) starts to contract (Aksyuk *et al.*, 2009; Aksyuk and Rossmann, 2011; Crowther *et al.*, 1977; Kostyuchenko *et al.*, 2003; Leiman *et al.*, 2004). The tip of the tail tube (gp5) punctures the cell, enters the periplasm and digests the cell wall (Browning *et al.*, 2012; Kanamaru *et al.*, 2002). The genome is then ejected into the host's cytoplasm by the tail tube. In phage T4 the pentameric protein forming 11 of the 12 vertices (gp24) has an HK97 fold, which has a high sequence similarity to T4 MCP (gp23) (Jiang *et al.*, 2003; Morais *et al.*, 2005).

Conclusion

Viruses are complex organisms that build extraordinary structures out of a limited number of building blocks. It is remarkable that the principles established by Watson and Crick (Watson and Crick, 1953b) and expanded by Caspar and Klug (Caspar and Klug,

1962) in the 1960s have been validated and still hold true for most virus structures discovered to date. Furthermore, it is worth noting that the large variety of virus structures that have been described in the scientific literature so far utilize a fairly small number of protein folds, most of which have been covered in this review. Improvements in sequencing technologies and less stringent isolation techniques have led to an immense increase in the number of viruses that have been described in the literature and it will be interesting to see if this increase eventually correlates with the discovery of new folds or new assemblies. It is already becoming clear that the future of structural virology will be dominated by cryoEM. Most of the recently determined virus structures were solved using this technique and one would expect this number to continue increasing. X-Ray crystallography will still play an important role, but will likely be confined to solving the structures of smaller components of virions or assemblies. In addition, cryoEM and cryoET will allow us to look into deviations of the strict symmetry requirements imposed onto most viral structures to date and help us to learn more about assembly pathways and unique structural components that might otherwise be overlooked. This might show us that viruses are not that perfect after all and may lead to important biological discoveries and potentially new therapeutic approaches.

Acknowledgments

MGR would like to thank all his many collaborators, post-docs, graduate students and colleagues who made it possible to accomplish many of the findings reported here. MGR is also grateful to the National Science Foundation, the National Institutes of Health and Purdue University for their generous support over many years. We thank Sheryl Kelly for her help in preparing the paper. MS and TK would like to thank MGR for the opportunity to co-write this article. This was the last paper MGR worked on and submitted a month before his tragic demise. It was an exciting time-travel through several decades of the history of structural virology.

Glossary

Icosahedral asymmetric unit The smallest part of the structure from which the complete structure of the virus can be built using a specific set of 60 rotational matrices that describe the 5:3:2 symmetry of the virus particle.

ICTV International Committee on Taxonomy of Viruses.

Quasi equivalence The interacting environment between subunits in an icosahedron with triangulation number

greater than 1 cannot be strictly equivalent, thus they are referred to as “quasi-equivalent” subunits.

SELEX A combinatorial chemistry technique in molecular biology for producing oligonucleotides of either single-stranded DNA or RNA that specifically bind to a target ligand or ligands and are commonly referred to as aptamers.

Triangulation number The number of facets (unique environments that subunits occupy) per triangular face of an icosahedron.

Introduction

Basic Structure

The proteins which form a protective shell around the viral genome (capsid) of a non-enveloped virus are multifunctional. The capsid must protect the genome integrity and release it into the target host cell, furthermore capsids may, depending on the host, mediate systemic transport across the host or between cells as well as host gene regulation and receptor-mediated endocytosis. In addition, for viruses of vertebrates the capsid outer surface is also the face the virus presents to the humoral immune system and largely defines its antigenic properties. Predicted in the early 1950s by Crick and Watson, the innate icosahedral symmetry of spherical capsids was established in the late 1950s when Don Caspar, Rosalind Franklin, John Finch and Aaron Klug obtained X-ray diffraction patterns of spherical plant viruses showing the presence of 5-fold symmetry. This was confirmed by the first high resolution structures of the small single-stranded (ss)RNA spherical plant viruses tomato bushy stunt virus (TBSV) and southern bean mosaic virus (SBMV), in 1979 and 1980 respectively.

An icosahedron has 12 vertices with 5-fold rotational symmetry, 20 triangular faces with 3-fold symmetry and 30 edges with 2-fold symmetry allowing the placement of 60 identical sub-units. Caspar and Klug proposed that the icosahedral asymmetric unit may be further triangulated to accommodate more subunits. The level of triangulation is denoted by a T number where the number of subunits is 60T. TBSV and SBMV adopted $T = 3$ architecture with 180 copies of the capsid protein forming three quasi-equivalent subunits (A, B, C) per icosahedral asymmetric unit. This gives rise to A/B dimers on the quasi 2-fold axes (around the 5-fold) which are bent and C/C dimers on the 2-fold axes which are flat, together generating the capsid curvature from what would otherwise amount to flat hexagonal close-packing. The dimer conformation is mediated by a conformational change in the flexible N-terminal arm which extends from the subunit core. The subunit core adopts a canonical eight-stranded jelly-roll β -barrel motif comprising 2 twisted β -sheets of 4 anti-parallel strands. This structure is pervasive across very many small viruses, and is often referred to as the viral jelly-roll. The strands of the two sheets are labeled (according to convention) alphabetically, following the amino-acid sequence from the N- to C-terminus as CHEF and BIDG; for the latter, strand labeling starts at B since TBSV has an additional strand outside the core fold. In the spherical capsid, the amino termini are on the inside, and particularly in plant viruses possess an N-terminal arginine rich motif which interacts with the negatively charged genome, the jelly-roll core lies parallel to the surface of the capsid, whilst the carboxy-termini are on the outside.

Picornaviruses were the first human viruses for which atomic resolution structures were obtained. Published in 1985, the structures of human rhinovirus 14 and poliovirus were a landmark in virology, being not only similar to each other but instantly perceived to have many core features in common with the plant virus structures, with the viral subunits comprised of a core jelly-roll domain. In these structures each of the 60 icosahedral ‘triangular’ subunits are sub-divided into 3, corresponding to the triangulation number $T = 3$, in exactly the same way as the plant viruses, but as each sub-triangle now contains a different protein (VP1–3) this is referred to as pseudo $T = 3$. The similarities in topology, detailed positioning of secondary structural elements and overall architecture led to the realization that structure was a more sensitive indication of evolutionary origin in viral proteins than their sequence. The structure of the insect virus, cricket paralysis virus provided a link between the plant and vertebrate viruses and confirmed evolutionary divergence. This underpins the basis for a higher-order classification of viruses and has led to the concept of a small ssRNA virus lineage ([Table 1](#)).

Diversity

The small ssRNA viruses infect organisms from different kingdoms but the same domain of life (Eukarya). The order *Picornavirales* classified according to the ICTV ([Table 1](#)) forms the major subset of this lineage. Members are largely non-enveloped (although

Table 1 Family members assigned by the ICTV for the Order *Picornavirales* and those assigned to a Picorna-like lineage by structure-based phylogeny

ICTV 2019 Order <i>Picornavirales</i>	Structure based Picorna-like lineage

	<i>Papillomaviridae</i>
	<i>Parvoviridae</i>
	<i>Picornaviridae</i>
	<i>Polyomaviridae</i>
	<i>Tetraviridae</i>
	<i>Tombusviridae</i>
	<i>Tymoviridae</i>

picornaviruses hepatitis A and E are quasi-enveloped, usually exiting the cell in vesicles), icosahedral, have diameters ~ 300 Å and pseudo $T = 3$ architecture. These viruses have one or a few positive sense ssRNA(s) genomes usually without overlapping open reading frames although the latter does not hold true for *Caliciviridae* and new families infecting arthropods (*Polycipiviridae* and *Soliniviridae*).

A major characteristic of this order includes the presence of a replication block comprised of 3 elements: a superfamily III helicase, a chymotrypsin-like proteinase and an RNA-dependent RNA polymerase. Whilst in the families *Picornaviridae* and *Iflaviridae*, the structural proteins are in the N-terminal region and replicative proteins in the C-terminal region of the polyprotein, the genomic organization is reversed in *Marnaviridae* (monocistronic) and *Dicistroviridae*, (dicistronic). In the family *Secoviridae* the replication block is either at the N-terminus of a monopartite genome or on a separate strand in a bipartite genome.

The topology of the capsid subunits is similar in all cases, with the termini forming a network of interactions maintaining particle integrity. However, there are distinctions in the assembly/disassembly pathways. Variations reflect different infection mechanisms e.g., via insect vectors or means to evade immune surveillance in animal hosts.

To derive phylogenies a similarity matrix is usually constructed from available sequences but in the case of the picornavirales which have single-stranded RNA(s) serving directly as mRNA the sequences change rapidly due to the error-prone replication mechanism and the process of selection. An alternative method for classification is defined by the Linnean approach of structure-based homology. The protein tertiary and quaternary structure being more constrained than its sequence, remains highly conserved despite substantial sequence variation and provides a complementary approach to deciphering the evolution of viruses. In a structure-based phylogenetic analysis, a similarity matrix is constructed based on pairwise superimposition of the various structures, with evolutionary distance being derived from the root mean square deviation between the matched residues divided by the fraction of the structure that is matched.

The structure of tobacco ringspot virus (TRSV), a plant nepovirus classified in subfamily *Comovirinae* (formerly family *Comoviridae*) of family *Secoviridae* revealed that the capsid protein comprises three β -barrel domains covalently joined by extended polypeptides reflecting the pre-cleaved states of the polyprotein of comoviruses which is cleaved into 2 capsid proteins and that of picornaviruses which is cut into 3 distinct coat proteins: this further confirms the notion of divergent evolution of the capsid polypeptides of nepoviruses, comoviruses and picornaviruses from a common ancestor. Structural similarity is highest with the cowpea mosaic virus (CPMV), another comovirus. CPMV particles are made up of a small protein equivalent to the picornavirus VP1 and a large coat protein corresponding to VP2 and VP3 joined into a single polypeptide.

Structure-based phylogenetic analyses have allowed assignment of further virus families to the single jelly-roll lineage that reaches beyond ssRNA + sense icosahedral viruses. This allowed the inclusion of the family *Birnaviridae* (capsids with $T = 14$ symmetry), *Bromoviridae* (3 genomic and 1 subgenomic ssRNA), *Luteoviridae* (ribosomal frameshifting expression strategy), *Microviridae* (ssDNA genome), *Nodaviridae* (bipartite ssRNA and a subgenomic RNA), *Papillomaviridae* (circular dsDNA and $T = 7$ dextro (right hand-skewed) symmetry capsids), *Parvoviridae* (ssDNA either + or -), *Polyomaviridae* (circular dsDNA, $T = 7$ d symmetry capsids), *Tetraviridae* (capsids with $T = 4$ symmetry), *Tombusviridae* (2 genomic and 2 subgenomic ssRNAs) and *Tymoviridae* (1 genomic and 1 subgenomic ssRNA) into the picorna-like lineage (Table 1).

Picornaviruses as an Exemplar Family

Picornaviruses (a family of vertebrate-infecting viruses with a positive ssRNA genome) have been well-studied structurally (Fig. 1) due to their importance to human and animal health. The largest genus within this family is that of the enteroviruses that use as

Fig. 1 Picorna-like virus capsids. a to d, HAV, FMDV, PV1 and TrV (PDB IDs, 4QPI, 1ZBA, 1HXS and 2NAP respectively). All capsids are shown in a surface representation colored radially as shown. An icosahedral asymmetric unit is outlined in black on a) with the 5-fold, 3-fold and 2-fold axes denoted by a pentagon, triangle and ellipse, respectively. e, Unrooted structure-based phylogenetic tree based on a selection of picornavirus structures representative of various genera from the PDB together with two insect picornaviruses (cripaviruses). CVB3, coxsackievirus B3; PV1, poliovirus type 1; HRV14, human rhinovirus 14 (RV-B14); BEV1, bovine enterovirus type 1 (EV-E1); EV71, enterovirus A 71 (EV-A71); TMEV, Theiler's murine encephalitis virus; MEV, mouse Elberfield virus also known as Mengo virus; SVV, Seneca valley virus; FMDV, foot-and-mouth disease virus; ERAV, equine rhinitis A virus; HAV, hepatitis A virus; AiV, Aichi virus; TrV, triatoma virus; CrPV, cricket paralysis virus.

the primary site of replication either the gastrointestinal tract (e.g., polio-, echo-, and coxsackieviruses), or the upper respiratory tract (rhinoviruses). Of the other genera, aphthoviruses include the causative agent of foot-and-mouth disease (FMDV) which infects split-hoofed animals, the genus name being derived from the Greek *aphtha*- meaning vesicles in the mouth. Cardioviruses cause myocarditis and encephalomyelitis in rodents which are considered to be their natural reservoir but their host range includes elephants, monkeys, pigs and humans. Hepatoviruses replicate in the liver of mammals and hepatitis A virus (HAV) the prototype of this genus is the only species that affects humans and primates. Parechoviruses and kobuviruses are more recently established genera; the first includes two species: Ljungan virus (LV), a virus of rodents and the human parechoviruses whilst the second is associated with gastroenteritis in humans, cattle, swine, sheep, goats, dogs, cats and mice with the genus deriving its name from the lumpy appearance of virus particles in electron microscopy; “kobu” meaning “knob” in Japanese. Overall enteroviruses are the most elaborate and best studied picornaviruses whilst hepatoviruses are likely to be much closer to the last common ancestor of picornaviruses.

Fig. 2 Picornavirus assembly. a, Capsid proteins of EV-A71 VP1–4 (PDB ID, 3VBH). The proteins are drawn as cartoons, with conventional protein coloring, to show the secondary structure elements in particular the β -barrel fold with the strands labeled CHEF and BIDG on VP1. The N- and C-termini are marked with blue and red spheres respectively. A lipid ‘pocket-factor’ is shown (in grey) bound within the hydrophobic pocket of VP1 b, The biological protomeric subunit (proteins depicted as in (a)). c, The pentameric subunit. d, A parechovirus pentamer drawn in surface representation with the proteins color coded as for EV-A71, viewed from the inside. Ordered RNA genome is shown in magenta around the 5-fold axis (PDB ID, 5MJV).

Capsid Assembly

The picornaviral positive-sense ssRNA genome (approx. 8K bases) is translated as a polyprotein and cleaved into the structural and replication proteins by encoded proteases. The polyprotein comprises three functional regions: P1, P2 and P3 with P3 proteins participating directly in genome replication and P2 proteins contributing to the host cell interactions required for virus multiplication, whilst the structural proteins form the P1 section at the 5′ end of the open reading frame. The polyprotein is divided into 1ABCD-2ABC-3ABCD units, where the numbers refer to the functional region and the letters to individual proteins. P1 adopts a three-dimensional fold prior to assembly (although no structure has thus far been determined for a picornaviral P1). This is then cleaved into VP0, VP3 and VP1 by the 3C protease (or 3CD precursor) to form 5S protomers. The cellular chaperone Hsp90 has been shown to be required for this processing in both entero- and aphthoviruses. The released protein termini associate to link five copies of each 5S protomer into a $\sim 14S$ pentamer and 12 such pentamers assemble to form a spherical shell 27–30 nm diameter (Fig. 2). Once the RNA has been encapsidated, VP0 undergoes an additional cleavage to produce VP4 (N-terminal) and VP2 to form mature virus particles.

VP1 proteins abut around the icosahedral 5-fold, and VP2 and 3 around the 2- and 3-fold axes whilst VP4 is internal. VP1–3 adopt the viral jelly-roll fold with the loops connecting the strands contributing to the external antigenic surface. Across the picornavirus family VP1–3 vary in size from approx. 24 kDa in FMDV to approx. 30 kDa in many other picornaviruses due to longer surface loops in the latter and more surface structure. This also results in variation in the capsid thickness between 33 Å for FMDV (excluding VP4) and 42.5 Å for human rhinovirus 14 (HRV14). In particular VP1 dominates the accessible surface forming extended loops around the 5-fold axis and in enteroviruses binds a lipid (pocket-factor) within a hydrophobic pocket in the β -barrel.

VP4 is much smaller than VP1–3 and has no core structure, rather it contributes to the extensive protein network on the inside of the capsid. The N-termini of VP1–3 also contribute to this network, knitting the protein cores together, often forming scaffold structures: they intertwine around the 5- and 3-fold axes with VP3 proteins contributing most towards the stability of the pentamer, through their N-termini associating around the 5-fold axes to form β -annuli. Extensions of VP4, VP2 (and VP1 in enteroviruses) contribute to stabilizing the interface between pentameric subunits by forming an extended β -sheet. In aphthoviruses this comprises six strands, the VP2 N-terminal hairpin (strands β A1 and β A2) of one pentamer together with the CHEF sheet of the β -barrel of a VP3 from an adjacent pentamer. Enteroviruses elaborate this further - the N- and C-termini of VP1 from the same protomer as the 'core' CHEF strands of VP3, sandwich the VP2 N-terminal hairpin from the adjacent pentamer. In parechoviruses a domain swap in VP2 sees this hairpin form on the two-fold related subunit instead of the VP2 from which it derives. This may explain why enteroviruses do not dissociate so readily into pentameric subunits but tend to form modified particles whilst for cardio and aphthoviruses, capsid integrity is vulnerable to low pH. The extreme lability of aphthovirus capsids also correlates with a greater number of histidines ($pK_a \sim 6$) at the pentamer interface.

The myristylation of the N-terminus of VP4 is a feature almost entirely conserved in picornaviruses (barring hepatoviruses and parechoviruses). In poliovirus, a hydrogen bond has been observed between the myristate carbonyl and the hydroxyl side chain of threonine 28 of VP4 (not conserved across all picornaviruses) between two 5-fold symmetry-related copies of VP4, thereby stabilizing the pentameric interaction. Ions have been visualized on the 3- and 5-fold icosahedral symmetry axes of a number of picornaviruses e.g., the DE loop (between β -strands D and E) of VP1 is involved in the interaction with a putative Ca^{2+} ion on the viral 5-fold axes in all analyzed rhinoviruses, which may play a role in regulation of stability although no conformational changes were observed in EGTA (chelating agent) treated virus structures.

In hepatitis A virus (HAV), 3 structural proteins are involved in capsid assembly: VP0, VP3 and VP1pX. pX a C-terminal extension of VP1 is required for efficient structural protein processing and virion morphogenesis is cleaved off by host proteases trypsin and cathepsin L in vitro to produce mature capsids. This is mirrored in CPMV a picornavirus-like plant virus, where the C-terminus of the protein equivalent to VP1 (called S protein) has been demonstrated to be required for RNA encapsidation and is also subsequently shed from mature capsids. Cryo-EM showed that the 24 amino acid peptide occupies the cleft between S protein subunits in the pentameric capsomere and stabilizes its structure by functioning as a dab of molecular glue: it acts as a molecular chaperone, that enhances the efficiency of folding/assembly but does not remain part of the final structure. In the case of HAV which is released in a quasi-enveloped form (eHAV) pX has additionally been shown to promote the secretion of virions through exosome-like vesicles by acting as a sorting signal for interaction with the host endosomal sorting complexes required for transport (ESCRT).

Genome Encapsidation

The picornavirus ssRNA genome (between 7.1 and 9.7 kb) is around 2.5 μ m in length and tightly packaged within the capsid (at a concentration of ~ 700 mg/ml). The precise details of genome encapsidation in picornaviruses are yet to be unraveled but variation is seen across the family. Whereas in most viruses no more than a few well-ordered RNA bases have been visualized in association with mature capsids (e.g., stacking with VP4 residues Tyr 20 and Phe 46 in poliovirus type 2 Lansing), the structures of the parechoviruses: human parechovirus 1 (HPeV1) and LV, revealed a stretch of relatively well-ordered RNA associated with the N-termini of VP3 (15 bases in LV) near the five-fold axes (Fig. 2). The VP3 N-termini of these viruses are uniquely rich in positively charged residues (arginine/lysine-rich motif) and a passive genome encapsidation mechanism has been proposed whereby VP3 acts as an RNA chaperone, organizing the genome into a condensed structure compatible with the icosahedral symmetry of the particle through numerous interactions with short RNA segments with pre-formed stem-loop structures (although largely electrostatic there is also specificity in these interactions). Such a mechanism would appear to be at variance with that put forward for enterovirus packaging which for poliovirus involves interactions between capsid and non-structural proteins in an RNA replication complex, but is not inconsistent with the observation of a 5'-terminal RNA stem-loop packaging signal (PS) in Aichi virus (genus Kobuvirus) and with that of a series of 5 degenerate RNA binding motifs in the 5'-terminal fragment of the plant virus, satellite tobacco necrosis virus. In the case of poliovirus, no PS could be identified in either the 5'- and 3'-non-translated regions, P1 or P2 regions of the genome, although rather weak PSs dispersed through the genome have not been ruled out.

The classical PS hypothesis assumes that a single PS site with affinity for cognate CP forms an RNA-CP assembly initiation complex. Through SELEX and bioinformatics analyses a series of up to 60 palindromic sequences could be identified throughout the genome of HPeV1 that bind to sites on the inside of VP3 and these are proposed to help direct assembly in a pathway mediated by the 2C ATPase, which can also act as a viral helicase. In vitro assembly studies showed that the CP does not bind spontaneously to RNA; the latter needs to actively fold into an assembly-competent conformation first. This could be achieved during replication when local secondary structures are favored as incomplete transcripts emerge from viral polymerases and in some picornaviruses, only nascent genomic transcripts are encapsidated. A complementary role for 2C would consist of RNA chaperoning and generation of the PSs. In summary whilst genome packaging remains poorly understood, for most picornaviruses it likely combines the use of dispersed PSs with specific protein chaperone interactions at the replication complex to achieve rapid genome collapse and encapsidation.

Many picornaviruses also assemble empty particles as part of a natural infection; these so-called natural empties are thought to be either a storage form of pentamers or a dead-end by-product of virion morphogenesis. Notably, natural empty particles are not

observed for parechoviruses which is in line with a distinct assembly mechanism. Recombinant empty particles, also called virus-like particles (VLPs) can be generated notably by co-expression of the capsid precursor polyprotein and the viral protease in heterologous systems and this is the focus of much research destined to produce new or safer alternatives to existing vaccines against e.g., FMDV, poliovirus and coxsackie viruses. One of the challenges is to compensate for the absence of internal RNA 'glue' and/or lack of VP0 processing by empirically discovered or rationally designed capsid protein mutations aimed at increasing VLP stability.

The maturation cleavage of VP0 into VP4 and VP2 upon RNA encapsidation occurs in all picornaviruses except kobuviruses and parechoviruses which may be related to the presence of ordered RNA density. This enigmatic cleavage is still assumed to be autocatalytic, being inaccessible to exogenous proteases. The subsequent rearrangement of the VP4 C-terminus and VP2 N-terminus confers stability on the particle and empty capsids containing VP0 are less resistant to heat and pH. The structure of natural empty capsids of poliovirus 1/Mahoney shows rearranging or disordering of the network on the inner surface. The VP0 cleavage site is located some 21 Å from the location observed in virions, the scissile bond being adjacent to a hydrophobic depression on the inner surface analogous to the binding site for icosahedrally ordered segments of the genomic RNA in the plant virus beanpod mottle virus. A possible mechanistic model for VP0 cleavage involves a conserved histidine residue located close to the VP0 cleavage site. Histidine 195 of VP2 (2195H) is hypothesized to activate local water molecules, thus initiating a nucleophilic attack at the scissile bond. 2195H mutants were nonviable and analyses showed that these particles contain genomic RNA and uncleaved VP0. In poliovirus immature empty capsid where the cleavage of VP0 has not occurred, VP0 residues near the cleavage site prevent the N-terminus of VP1 from accessing its position in the mature particle where it would interact with the inner surface of VP2 and VP3 contributing to particle stability. In contrast, empty capsids of FMDV type A22 Iraq 24/64 contain VP2 and VP4. The disordering of the internal network in these FMDV empty capsids is less extensive than that seen in the poliovirus empty capsid, which has VP0 intact. Thus, VP0 cleavage confers stability on the picornavirus capsid over and above that attributable to RNA encapsidation. His 2145 in FMDV VP2 appears to be analogous to His 2195 in poliovirus and similarities in the putative active site support the cleavage hypothesis. This final stage in assembly is thought to establish a metastable state, priming the particle to initiate the entry process when receptor interactions and/or reduced pH trigger the conformational transition to a lower energy state.

Host Interactions

Virus capsids recognize susceptible cells by attachment to specific receptors on the plasma membrane thereby determining the host range and tropism of infection. Although many cellular receptors have been identified and structural analyses of virus-receptor complexes have provided insight into the initial stages of this interaction, subsequent events remain unclear (Fig. 3). Picornaviruses generally gain entry to the cytoplasm via an endocytic vesicle and often require complex receptor/co-receptor interactions to deliver them to appropriate sites on the cell surface for the induction of endocytosis.

Clues about receptor interactions came from the very first enterovirus structures. As one of the loops around the five-fold axis, the BC loop of VP1 forms a projecting ridge in enteroviruses. The depression beyond it encircles the five-fold axis and is bounded at the southern side by the GH loop and C-terminus of VP1. For HRV14, this approximately 12 Å depression was named the 'canyon' and hypothesized to correspond to the receptor binding site since its dimensions made it inaccessible to antibodies, suggesting a mechanism by which the virus could evade immune surveillance. Rhinoviruses are classified into major and minor

Fig. 3 Picornavirus receptor complexes. a, A surface representation of the EV-A71-SCARB2 (6I2K) complex with the capsid proteins colored as in Fig. 2. SCARB2 is shown in gray binding at the southern edge of the canyon depression and does not occlude the canyon. b, A similar view of the poliovirus-CD155 (3J8F) complex, note the receptor inserts into the canyon.

receptor-binding groups. Major group rhinoviruses e.g., HRV14 and HRV16 recognize the ICAM-1 receptor, and structural results show that it binds within the canyon. However, key viral amino acid residues involved in binding ICAM-1 are also accessible to antibodies; i.e., the receptor site is not effectively hidden and several antibody/virus complexes show antibodies binding across or partially within the canyon.

Similarly, the binding site of the poliovirus receptor (PVR), the nectin CD155 has been visualized in the canyon (Fig. 3). Cryo-electron microscopy and image reconstruction of receptor-poliovirus complexes reveal PVR binding to the 'wall' of surface protrusions surrounding the 'canyon' in a more tangential orientation than ICAM-1. The greater exposure of the receptor-binding sites in polioviruses compared to rhinoviruses makes them less protected from immune surveillance but well suited for receptor-mediated virus uncoating and entry at the cell surface.

The coxsackievirus B3-receptor (CAR; coxsackie and adenovirus receptor) also binds in the canyon, with the distal end of its N-terminal Ig-like domain, but its binding orientation relative to the viral surface is quite different. In the coxsackievirus B3-full length CAR complex the transmembrane and cytoplasmic regions of two adjacent CAR molecules related by icosahedral two-fold axes associate with each other which increases the receptor binding avidity to the virus without altering the orientation of the CAR domains on the viral surface. Coxsackie B viruses bind both decay-accelerating factor (DAF) and CAR and as their respective footprints on the viral surfaces do not overlap each other, they could be used simultaneously in cell entry. In contrast in the echovirus 7-DAF receptor complex, the DAF molecules bind across the icosahedral two-fold axes, not in the canyon. Since the binding of echovirus 7 to DAF is reversible, this is consistent with DAF being an initial attachment receptor triggering signal-dependent transport of the receptor-virus complex to CAR located in the tight junctions of epithelial cells so that binding and cell-entry can occur.

For enterovirus 71 (EV-A71) responsible for hand, foot-and-mouth disease (HFMD), two receptors have likewise been identified: human P-selectin glycoprotein ligand-1 (PSGL-1), a mucin-like protein that serves as a receptor for the infection of leukocytes and scavenger receptor class B member 2 (SCARB2; lysosomal integral membrane protein-2) which mediates uncoating at low-pH. A complex with the latter was obtained using a low-pH stabilized mutant of EV-A71 further stabilized using a drug candidate to replace the lipid pocket-factor. SCARB2 binds on the southern rim of the canyon rather than across the canyon as predicted. Whilst 12 of the 14 residues involved in receptor binding are conserved across EV-A71 genotypes, only 10 are conserved in other viruses that use SCARB2 as a receptor, likely arising from antigenic variation. Another enterovirus causing HFMD, Coxsackievirus A10 (CV-A10) recognizes Kringle-containing transmembrane protein-1 (KREMEN-1). This rather large molecule binds across the canyon (although it doesn't fully reach the canyon floor) spanning two adjacent asymmetric units via its KR (Kringle) and WSC (carbohydrate binding) domains. CV-A10 makes interactions using the VP1 EF and GH loops and C-terminus together with the VP2 EF loop. The residues involved in receptor binding are mostly conserved in Kremen-1 dependent enteroviruses suggesting a similar mode of binding. Echovirus 30 (E30) which causes human aseptic meningitis, utilizes DAF (CD55) and also FcRn (Neonatal Fc receptor) as attachment and uncoating receptors. Structural studies of complexes showed CD55 binding outside the canyon extending south (akin to EV-A71/SCARB2) with little change in the viral capsid. FcRn in contrast, bound within the canyon to the VP1 BC, VP1 GH and VP2 EF loops. Enteroviruses can be sub-divided on the basis of their capsid structure, in particular the canyon morphology which correlates with their receptor usage suggesting that receptor switching drives evolution in these viruses.

In cardiociruses, e.g., Mengovirus, a depression similar to the 'canyon' exists except that it is not continuous but broken into five deep pits located in the region homologous to the deepest portions of the rhinovirus canyon. The remainder of the canyon is filled by two insertions (loops I and II between β C and β D of VP1). Another cardiocirus, persistent Theilers Murine Encephalitis Virus (TMEV) uses sialic acid as a receptor moiety. Crystallographic analysis shows the receptor mimic sialylactose to bind to a negatively charged pocket on the viral surface composed mainly of residues of puff B from capsid protein VP2, in the vicinity of the VP1 loop II and VP3 C-terminus. The putative receptor binding site for cardiociruses, the 'pit' (analogous to the canyon) is about 15 Å from this sialic acid binding site.

In contrast to the rhinovirus major group, minor group viruses bind members of the LDL-receptor family including the very low-density lipoprotein receptor (VLDL-R). A 15 Å resolution cryo-electron microscopy analysis of human rhinovirus 2 (HRV2 or RV-A2) complexed with the first three (of eight) ligand-binding repeats of VLDL-R showed the receptor to bind to the star shaped dome on the icosahedral 5-fold axis rather than in the canyon. The footprint of the first two domains of VLDL-R on the viral surface (domain three does not contact the capsid) overlays the BC- and HI- loops of VP1. X-ray structures of HRV2/VLDL V3 concatamers demonstrated multi-modular binding around the five-fold axes. Receptor specificity is thought to arise from hydrophobic interactions between a conserved lysine on the virus and a tryptophan in the receptor modules together with coulombic attraction.

FMDV differs from the entero and cardiociruses in having a relatively smooth surface, with one exceptionally long exposed loop, the GH-loop of VP1 (residues 134–160) which not only constitutes a major antigenic site but also contains a conserved RGD (Arg–Gly–Asp) sequence which is essential for cell attachment via an integrin receptor, predominantly $\alpha_v\beta_6$. This loop is highly disordered in the native virus structure of all serotypes examined to date. When the disulfide bond that links the base of the loop in strain FMDV-O₁ (Cys134 to Cys130 of VP2) is reduced, the loop adopts a more highly ordered position lying along the viral surface. The fully open form of the integrin has been visualized in different poses attached to the VP1 GH loop which is extended away from the virus surface. The integrin binds almost perpendicular to the virus surface. Whilst the flexibility of the VP1 GH loop precludes a high resolution structure determination the binding can be inferred to occur via interactions with the RGD motif and

downstream hydrophobic residues. In addition, an N-linked sugar on the integrin attaches to a heparan sulfate binding site on the virus.

FMDVs repeatedly passaged in tissue culture adapt to use heparan sulfate, a glycosaminoglycan (GAG), as a receptor. Crystal structures of both serotype O1BFS and A1061 with this GAG show that it binds with high affinity by immobilizing a specific highly abundant motif of sulfated sugars in a shallow depression on the virion surface, located at the junction of the three major capsid proteins, VP1, 2 and 3. In both serotypes, residue 56 of VP3, an arginine, is critical to this recognition, switching from a histidine in field isolates in adaptation to tissue culture. In the infected animal there may be a biological advantage to low affinity, or more selective, interactions with GAG receptors.

Uncoating

There appear to be two modes of receptor interactions with picornaviruses (1) that exemplified by most enteroviruses where receptor binding facilitates, by a quasi-mechanical effect, the formation of an altered capsid which is thought to commit the virus to uncoating and (2) that exemplified by cardio- and aphthoviruses where the receptor interaction is more surface orientated and appears to be a simple attachment with low pH instigating dissociation. All picornaviral capsids are balanced between stability and instability - they must be sturdy enough to allow the virus to pass from host to host through a hostile environment (especially enteroviruses which infect via the gut) and able to readily uncoat and release their RNA upon cell entry.

In enteroviruses the interaction with receptor initiates irreversible structural changes starting with dislodging the fatty acid pocket factor and ultimately leading to the exit of the N-terminus of VP1 and VP4 to form the expanded intermediate or 'A-particle'. This appears to correspond to the dominant form of the virus found in cells early in infection and is thought to be a necessary transitional state in the cell entry process. This particle exhibits changes in sedimentation behavior (from 160S to 135S), antigenicity and protease sensitivity, has increased hydrophobicity and readily attaches to liposomes. The A-particle is endocytosed and at some point, engages fully with the vesicle membrane to deliver the RNA to the cell, leaving an empty 80S or B particle. In recent years knowledge of the structure of the 135S particle and its formation has advanced significantly. For example, in EV-A71 the virus VP1 GH and VP2 EF loops interact with helices $\alpha 5$ and $\alpha 7$ of receptor SCARB2, part of a helix bundle that undergoes low-pH dependent conformational changes. The GH loop of VP1 is proposed to act as a sensor in a sensor-adaptor uncoating mechanism for enteroviruses and it seems likely that a low-pH induced conformational change in the receptor acts as a trigger for this mechanism. Likewise, KREMEN-1 binding by CV-A10 at low pH elicits virus uncoating *in vitro* utilizing a similar mechanism where the receptor induces flexibility in the VP1 GH sensor loop facilitating pocket factor release and the structural re-arrangements leading to the formation of the 135S particle. This intermediate particle for CV-A16 has been captured in a crystal structure with the N-terminus of VP1 in egress from the particle (Fig. 4). As for other 135S particles, the capsid is expanded ($\sim 4\%$), the pocket factor absent and the VP1 β -barrel collapsed, VP4 and the N-terminus of VP1 are missing from the interior, the paired helices on the 2-fold axis each from a 2-fold related VP2 molecule are pulled apart opening a '2-fold channel' and a smaller channel forms close-by at the base of the canyon, the 'off-axis channel'. However, in this structure, the 'off-axis channel' is plugged by residues 71 to 65 of VP1 passing through the capsid with residue 62 the last seen on the particle surface, the first 61 residues assumed disordered. The 'off-axis channel' is formed by a conformational change in the GH-loop of VP3 from a helix in the mature capsid to a β -hairpin in the expanded state. The enlargement of the '2-fold channel' is achieved by re-orientation of side-chains triggered by reorganization of the C-terminus of VP2. Residues separating the two channels are also seen to become much less well-ordered. The RNA appears condensed and packed in layers, rather than evenly distributed as observed in mature virions.

Fig. 4 Picornavirus uncoating. a to c, coxsackievirus A16 (CV-A16) virion (5C4W), expanded CV-A16 empty capsid (6LHC) and CV-A16 A-particle (4JGY) with extruded N-terminus colored in magenta. The capsids are depicted as in Fig. 1. The use of consistent radial coloring across all panels shows the capsid expansion.

There is a 15 Å gap between the capsid and RNA where the N-terminal protein network existed and bridging electron density is seen between the capsid and RNA apparently close to the N-terminal end of VP1 and N-terminus of VP2. The extruded segment of VP1 harbors an amphipathic helix and in conjunction with the myristoyl-VP4, is proposed to facilitate cell entry by forming a pore in, or disrupting, the endosomal membrane for egress of the RNA. At least a sub-set of the changes that occur on 135S conversion are reversible since there is evidence that mature poliovirus particles can 'breathe' leading transiently to the externalization of internal polypeptides, as captured by electron microscopy using an Fab directed against the N-terminus of VP1. For these studies, entry intermediates have been produced *in vitro*, for instance by incubating the virus at high temperatures or with excess solubilized receptor molecules. An alternative approach has been used to induce the coxsackievirus B3 entry intermediate by triggering a conformational change in the virus with full-length receptors embedded in lipid bilayer nanodiscs. Thus, rather than decorating a particle such that many or all of the receptor binding sites are occupied, asymmetrically decorated particles more akin to *in-vivo* cell-entry are formed. A-particles generated in this way have been reconstructed using cryo-electron microscopy with and without imposing icosahedral symmetry at 3.9 and 7.8 Å, respectively. In contrast to the A-particles described above, asymmetric receptor binding leads to minimal global capsid expansion but more concerted conformational changes at the site of receptor interaction with viral proteins extruded from the capsid only at this unique site adjacent to the nanodisc.

For cardio- and aphthoviruses, in contrast, there is no evidence for receptor-binding induced conformational changes and it has been thought that these viruses dissociate directly to pentamers at low pH. Disruption into pentamers under the influence of reduced pH in the endosome would render safe transfer of RNA to the cytoplasm very problematic. An apparent link to the enterovirus mechanism was revealed by the analysis of the aphthovirus equine rhinitis A virus (ERAV), which showed that acid-driven disassembly into pentamers proceeds via a quasi-stable 80S empty particle. This putative intermediate in the cell entry process is not a peculiarity of ERAV since intact, empty FMDV particles missing both RNA and VP4 have also been observed, at least transiently. A low pH ERAV crystal structure presumed to correspond to the 80S particle observed biochemically, shows changes restricted to internal features affecting particle stability e.g., there is the movement of the N-terminus of VP1 (corresponding to residues 44–56 in poliovirus) to the pentamer interface, displacing the N-terminus of VP2, which becomes disordered. The structure of a low pH form of the acid-dissociable Mengovirus, a cardiovirus, also shows very few conformational changes compared to the native structure: it appears that there are simply changes in the receptor binding 'pit' which would be consistent with a loss of receptor binding prior to direct involvement with the membrane. Loss of receptor binding has also been reported for enteroviruses HRV2 and poliovirus and may be a generic feature of picornavirus cell entry.

In poliovirus the final structural rearrangements to form the mature capsid involve similar structures to those externalized reversibly when the virus 'breathes' and irreversibly in receptor-mediated conformational rearrangements early in the entry process. That the changes in ERAV correlate strongly with this suggests that cleavage and reorganization to prime the virus for the conformational changes required for cell entry is a general principle in all picornaviruses. Also, the ability to eject the genome while maintaining icosahedral integrity is a feature common to both aphtho- and enteroviruses and suggests that there may be a general mechanism by which all picornaviruses protect their genome within intact capsids until the moment it is safely transported into the cytoplasm. However, there is still much to be learnt about the structural basis of cell entry, not least since none of the structures observed to date explain how a heavily structured RNA genome is transported intact, without expending chemical energy, into the cytoplasm of the host cell and the uncoating of highly stable picornaviruses such as hepatitis A virus remains an enigma.

Antiviral Drugs

The VP1 β -barrel of enteroviruses contains a hydrophobic pocket which, in some structures is occupied by endogenous lipids (cofactors known as 'pocket factors') that have been variously modeled as e.g., sphingosine, lauric acid, myristic acid. Crystallographic analyses revealed that hydrophobic antiviral 'WIN' compounds bind tightly to this pocket, displacing any natural pocket factor. The entrance to the pocket is at the bottom of the canyon and the antiviral agents lie roughly parallel to the floor of the canyon, the inner end of the pocket being lined by residues more hydrophobic than those towards the pore. In addition to major and minor receptor binding groups, rhinoviruses are classified into antiviral groups A and B according to their sensitivity to 15 antiviral compounds, group A being more sensitive to long antiviral compounds and group B to short antiviral compounds. Minor group viruses all belong to group B and the similar amino-acid composition in the pocket suggests that these viruses may all contain pocket factors. These hold the pocket "open" and in the case of human rhinovirus 1A (HRV1A) (group B) on binding of antiviral compounds only small conformational changes are seen. Larger conformational changes occur with all anti-viral compounds on binding to HRV14 (group A) - principally involving a movement of the VP1 GH loop upwards into the canyon. Potential antiviral inhibitors block virus replication in two ways: (1) they prevent virus uncoating and the release of viral RNA, by filling the hydrophobic pocket within the β -barrel of VP1 and stabilizing the virion, (2) they reduce receptor binding. WIN resistance mutations occur within the pocket, usually involving a change to a larger hydrophobic residue, blocking antiviral entry. Only enteroviruses seem to be susceptible to this class of drugs since in aphthoviruses and cardioviruses the pocket is filled by bulky sidechains. These studies have led to the discovery of potential drugs, for example Pleconaril (WIN 63843) which was aimed at the prevention of asthma exacerbations and common cold symptoms and completed phase two clinical trials in 2007 but is not licensed for use owing to the potential for multiple drug interactions.

A novel 'pocket-factor mimic' compound was rationally designed based on analysis of complexes of EV-A71 with four 3-(4-pyridyl)-2-imidazolidinone derivatives with varying anti-EV-A71 activities. Key structure-activity correlates were used as guides for

potentially beneficial substitutions and methods developed to reliably triage these compounds by quantum mechanics-enhanced ligand docking. Two candidates were synthesized, and structural analyses and in vitro assays confirmed the predicted binding modes and their ability to block viral infection. One ligand (with IC₅₀ of 25 pM) was an order of magnitude more potent than the best previously reported inhibitor and also more soluble. This structure-based approach may be useful for further design of effective drugs for enterovirus infections.

A recent cell-based antiviral screen against Coxsackievirus B3 (CVB3) led to the identification of compound 17, a benzene sulfonamide derivative, as a potent in vitro inhibitor. Its binding site was identified by cryo-EM as being a pocket formed by two VP1 and one VP3 protein at the interface between protomers. This positively-charged surface depression is conserved across many enteroviruses and has been identified as a binding site for glutathione which has an essential role in the formation of the pentameric subunit since bound glutathione makes strong interactions with adjacent protomers. This explains the underlying biological role of this binding pocket and opens the possibility for the rational design of antiviral drugs targeting this site. In fact, since this second druggable pocket is separated from the VP1 hydrophobic pocket by 16 Å, complementary antiviral effects might be achievable.

Antiviral drugs may also target the non-structural proteins; the 3C protease and 2C ATPase have been targets for the design of broad-spectrum drugs. However, the first line of defense against a viral attack is the immune response directed at epitopes at the capsid surface.

Antigenicity and Antibody Interactions

Locating the sites of escape mutations for resistance to neutralisation by monoclonal antibodies was traditionally used to map epitopes to the virus surface. Escape mutations often occur repeatedly at only a few residue positions and for FMDV-C, structural studies have shown that they address amino acids not involved in interactions with other capsid residues, suggesting that they are not required for maintenance of the capsid structure and since the virus remains viable, they are not required for another essential biological function. This applies to receptor binding sites in exposed locations such as the FMDV GH loop where amino acids adjacent to the key receptor binding residues can readily mutate without compromising the viability of the virus particle, although they may even switch the conformation of this immunodominant loop. Many picornaviruses possess 4–6 distinct antigenic regions and there is some correspondence between different viruses. It is, however, likely that the majority of the virus surface is antigenic. Whilst epitopes may comprise residues from disparate parts of the same, or different proteins, they cluster in surface patches, usually corresponding to variable surface accessible sequences. The flexibility of continuous epitopes located in antigenic loops provides a vehicle whereby, by switching loops from one virus into another, it has been possible to produce particles that possess antigenic properties in common with two different viruses. Such chimeric viruses may present possibilities for more broadly protecting vaccines.

Understanding the mechanisms by which antibodies neutralize picornaviruses and, conversely, how viruses escape from antibody recognition requires a detailed knowledge not only of the virus structure but also of the virus–antibody interactions at the amino acid level. Studies of viral peptide–antibody complexes and picornavirus–Fab complexes by X-ray crystallography, cryo-electron microscopy or a combination of the two techniques, have built on the data from escape mutant analyses.

The surface area on HRV14 in contact with Fab17-IA, the antibody footprint, was estimated to be approximately 500 Å² - much larger than the NIIm-IA neutralizing immunogenic epitope defined by escape mutants: in addition to antigenic residues which are tolerant to change through escape mutation, some invariant residues that may be critical for virus structure also make antibody contacts.

Antibodies neutralize virus infectivity by a variety of mechanisms other than simply interfering with infection by binding to cell attachment sites on the virion, for example, altering virus stability, preventing uncoating, or cross-linking viruses causing aggregation. Neutralization titration curves indicate three categories: strong, intermediate and weak. The majority of antibodies are weak neutralizers that function by using the two arms of the antibody to cross-link different virus particles giving rise to aggregation. The strong/intermediate neutralizers show a monotonic decrease in the amount of surviving virus as the antibody to virus ratio increases and may neutralize by blocking the receptor binding site, interfering with cell attachment.

For the strongly neutralizing mAb17-IA binding to HRV14, 5–6 mAbs/virion are sufficient to block cell attachment by 50%. The complex structure shows that the Mab binds bivalently across an icosahedral 2-fold symmetry axis. Since all 60 receptor binding sites cannot be blocked, the mechanism of neutralization may be by preventing structural changes necessary for receptor attachment and indeed no significant changes were seen in capsid structure. The C3 neutralizing antibody for poliovirus binds to the analogous site, a peptide corresponding to the BC loop of VP1 (though varying in length, structure and sequence from that in HRV14). Both structural and biochemical studies indicate that there are differences in the modes of binding and mechanisms of neutralization of the two antibodies. C3 neutralizes poliovirus 1 at a low Ab: virus ratio and no reduction in attachment to cells is seen. It may neutralize by causing significant local alterations in the antigenic site and prevent structural changes subsequent to receptor attachment that are necessary for cell entry or uncoating.

In the SD6 Fab/FMDV-CS8 complex, the Fab projects almost radially from the viral surface in an orientation only compatible with monovalent binding of the mAb to its GH-loop epitope in what is termed the 'up' position close to the capsid 5-fold axis, the 'down' position being closer to the capsid 2-fold axis. Even taking into account antibody flexibility, it was not possible to model bivalent binding without severe distortion. Although this might suggest that SD6 driven aggregation is the mechanism of

Fig. 5 EV-A71 and antibody 38-3-11A Fab complex (6Z3P). a) The virus capsid is shown as a surface representation with the proteins colored as for Fig. 2(a). The Fabs are also shown as a surface representation with the heavy chains in magenta and light chains in cyan. b) A roadmap (flattened surface representation of the virus surface where residues are drawn to size according to their accessible surface area). The Fab footprints are shown by enhancing the color of the capsid proteins to which they bind. c) As a) but showing SCARB2 (gray) binding in the context of the Fab complex.

neutralization, this is not the full story since the SD6 GH-loop epitope includes the integrin binding motif and the Fab alone acts as a strong neutralizer, presumably by interfering with cell attachment. The SD6 Fab shows induced fit conformational changes on binding the FMDV GH-loop epitope, to create a complementary pocket. This feature is also observed in the complex between the weakly neutralizing antibody 8F5 and a contiguous epitope at immunogenic site N1m B, from VP2 of HRV2. This complex shows bivalent binding across the icosahedral 2-fold axis and demonstrates that bivalent binding does not ensure strong neutralization.

In recent years, the development of techniques for single cell sorting followed by RT-PCR and sequencing have allowed immunoglobulin (Ig) heavy (H) and light (L) chain matching from isolated peripheral blood mononuclear cells (PBMCs). This enables recombinant expression and characterization of large numbers of antibodies derived from the real hosts of viruses. Six complementarity determining regions (CDRs), 3 each in the variable (V) domain of the H and L chains determine the specificity and affinity of an antibody. Of these, VH CDR3 is the most variable and plays a dominant role in recognizing and binding antigens; in mice this region is shorter and potentially less able to explore key areas of human epitopes, emphasizing that Ig repertoire studies using animal models can be misleading. When a large panel of mAbs derived from antibody secreting cells of several EV-A71-infected children were analyzed, potency and breadth of neutralisation of different virus genotypes could be correlated to epitope localization on the virus capsid: antibodies binding to the floor and rims of the capsid canyon were more effective than those mapped to the 3- and 2-fold so called plateau epitopes on the margin of pentamers (Fig. 5).

Conclusion

Structural analyses have now been completed for many small ssRNA viruses, and in particular studies of picornaviruses have highlighted similarities and differences between the genera relating to their biological properties. Indeed, structure-based phylogenetic analysis reveals the relative distance of the parecho and kobu genera from the entero, aphtho and cardio genera and places HAV within the wider picornavirales between typical 'modern' picornaviruses and the more primitive precursor insect viruses reflecting its enigmatic properties. These advances in our understanding of this lineage of viruses take us from the fundamental biology of the virus life-cycle and evolution to the potential for rationally designed antivirals and vaccines.

Introduction

Flaviviruses cause some of the most devastating arthropod-borne diseases around the world, including dengue hemorrhagic fever, yellow fever, Zika disease, Japanese encephalitis, West Nile encephalitis and tick-borne encephalitis (Huang *et al.*, 2019). The emergence and spread of flaviviruses into new geographical areas pose substantial public health challenges for multiple countries. Important progress has been made in understanding the structural organization of the flavivirus particles and the way their envelope proteins function during the virus life cycle, providing crucial knowledge for the development of rational approaches to cure and/or prevent these diseases. Yet many aspects of the flavivirus particle assembly process remain not understood.

The flavivirus molecular biology era began with the determination of the full nucleotide sequence of the yellow fever virus genome in 1985 (Rice *et al.*, 1985) and was pursued with structural biology ten years later with the high-resolution X-ray structure of the envelope protein E of the tick-borne encephalitis virus (TBEV) (Rey *et al.*, 1995) and later that of dengue virus type 2 (DENV2) (Modis *et al.*, 2003). These structures corresponded to the ectodomain of the pre-fusion E dimer, i.e., the form present at the surface of infectious particles. The structures of the E trimer ectodomain soon followed (Bressanelli *et al.*, 2004; Luca *et al.*, 2013; Modis *et al.*, 2004) – i.e., in the conformation adopted after the functional reorganization of E required to drive the fusion of the viral envelope with an endosomal membrane for entry into a target cell. A further important landmark was the X-ray structure of the DENV2 prM/E heterodimer present in immature flavivirus particles (Li *et al.*, 2008). The first cryo-electron-microscopy (cryo-EM) structure of a mature virion to a resolution sufficient to resolve the individual E dimers at the particle surface was reported in 2002 (Kuhn *et al.*, 2002). This pioneering work was followed by the cryo-EM structures of mature DENV2 particles at a nominal resolution of 3.5 Å reported in 2013 (Zhang *et al.*, 2013) – at a time when the direct electron-counting detectors (McMullan *et al.*, 2016) that led to the present day “resolution revolution” in single-particle cryo-EM (Henderson, 2015) were not yet available. A number of important cryo-EM structures have been reported since then, such as the structures of the mature particles of DENV4 (Kostyuchenko *et al.*, 2014), Zika virus (ZIKV) (Kostyuchenko *et al.*, 2016; Sirohi *et al.*, 2016), Japanese encephalitis virus (JEV) (Wang *et al.*, 2017) and TBEV (Fuzik *et al.*, 2018) at around 4 Å resolution, culminating in 2018 with the refined structure of the ZIKV mature particle at 3.1 Å resolution (Sevvana *et al.*, 2018). The structures of immature flavivirus particles were also determined by cryo-EM, albeit to lower resolution, the best defined one was that of DENV1 at 6 Å resolution (Kostyuchenko *et al.*, 2013).

In this article, we examine the interactions between the viral glycoproteins at the particle surface, with a particular emphasis on the immature particle at neutral pH – the form in which it accumulates in the ER of the infected cell, before transport through the secretory pathway. We describe this icosahedral surface lattice as an intertwined network of E triskelions that are crosslinked by prM, and analyse the major conformational change it undergoes at acid pH. We then examine the geometric construction leading to the peculiar icosahedral neutral pH immature particle, and identify that a key feature of this organization is an empty position in the corresponding icosahedral lattice. We further show that the thermodynamic relation between the two immature lattices – at neutral and acid pH – can be explained in terms of the 532 symmetry point group within the framework of the Landau “weak crystallization theory” as implemented by (Rochal *et al.*, 2016).

The Flavivirus Precursor Polyprotein and the Derived Structural Proteins

The flavivirus genome (Fig. 1) is a single-stranded RNA molecule about 11,000 nucleotides long containing a single open reading frame (ORF) flanked by 5′ and 3′ untranslated regions (UTRs) that control its replication in the infected cell (Pierson and Diamond, 2013). In a first step, the genome acts as a messenger RNA directing its translation by cellular ribosomes. In a subsequent step, it directs the production of full-length antigenomic copies by the newly translated viral polymerase to serve as replication template. The translation of the flavivirus genome by cellular ribosomes yields a single, virtual polyprotein precursor about 3400 amino acids (aa) long (Fig. 1(A)) that crosses the ER membrane several times. This polyprotein is virtual because it undergoes autocleavage before translation is complete, together with processing by host proteases such as ER membrane resident signal peptidases and by an additional virally-encoded protease to yield the individual viral proteins (Pierson and Diamond, 2013). The three proteins composing the flavivirus virion – i.e., the “structural” proteins – are derived from the N-terminal third of the precursor, while its remainder yields the non-structural (NS) proteins, which are essential viral proteins present in the infected cell (including the replication enzymes, Fig. 1(A)) but which are not incorporated into particles.

Some NS proteins are integral membrane proteins spanning the ER membrane multiple times, while others are peripherally associated with the membrane via protein-protein interactions on the cytosolic side. The latter group includes the two main replication enzymes, the viral protease/RNA helicase NS3 and the methyl transferase/RNA polymerase NS5 – reviewed by (Tay and Vasudevan, 2018). The only non-cytoplasmic NS protein is NS1, which forms membrane-associated dimers (Akey *et al.*, 2014) that

Fig. 1 Flavivirus polyprotein precursor and derived structural proteins. (A) The flavivirus genome is a messenger RNA molecule with a single open reading frame (ORF) (top, boxed) coding for a polyprotein precursor of all viral proteins. The ORF is flanked by highly structured untranslated regions (UTRs) that are required for genome replication. The mature viral proteins are indicated within the ORF box, roughly to scale. The structural proteins, colored differently in the top diagram, are enlarged in the second panel to show the various domains of protein E. (B) The flavivirus capsid protein C dimer. One of the chains is colored gray while the other is ramp-colored from N- to C-ter according to the color-key. Note that the α -helices from both chains are involved in creating a single tertiary structure. There is a non-polar face predicted to contact the viral membrane, and a basic face predicted to interact with the genomic RNA. The structure displayed corresponds to the 1.9 Å X-ray structure of ZIKV C (Shang *et al.*, 2018). (C) The prM/E heterodimer derived by docking the X-ray structure of the DENV2 pr/E complex at 2.2 Å resolution (Li *et al.*, 2008) into a new reconstruction of immature flavivirus particles to 4.4 Å resolution (PDB:XXXX, F. Coulibaly, personal communication). prM is represented in gray whereas E is shown ramp colored according to the key in panel B. The furin cleavage site in prM is indicated. (D) The mature (M/E)₂ dimer, as extracted from the refined 3.1 Å resolution cryo-EM structure of the ZIKV virion (Sevvana *et al.*, 2018), presented in top (upper panel) and side (lower panel) views. The individual domains of E are labeled, and the location of the fusion loop (FL), buried at the E dimer interface, is indicated. In the side view, the viral membrane is schematized in brown/beige. (E) The post-fusion E trimer. The subunit in the foreground is shown as colored ribbons (as in D) and the two subunits in the background in surface representation in two different shades of gray. The predicted location of the fused membrane is indicated, into which the fusion loops are inserted. Reproduced from Klein, D.E., Choi, J.L., Harrison, S.C., 2013. Structure of a dengue virus envelope protein late-stage fusion intermediate. *Journal of Virology* 87 (4), 2287–2293. doi:10.1128/JVI.02957-12.

participate in the replication complex – albeit from the ER luminal side – via interactions with other TM NS proteins such as NS4B (Mackenzie *et al.*, 1996; Youn *et al.*, 2013, 2012). A fraction of NS1 is secreted as hexamers from infected cells (Gutsche *et al.*, 2011). Once sufficient viral proteins have accumulated in the cell, the viral genome is replicated by the viral polymerase and associated NS proteins. Although the molecular details are not understood, genome replication occurs within invaginations of the ER membrane (Junjhon *et al.*, 2014; Welsch *et al.*, 2009).

The three structural proteins of the flaviviruses are depicted in Fig. 1(B)–(D): the capsid (C) protein, which is roughly 100 aa long (depending on the flavivirus), and two transmembrane glycoproteins: the precursor Membrane protein (prM, ~170 aa, Fig. 1(C)) and the Envelope protein (E, ~500 aa, Fig. 1(C)–(E)). The cytosolic C protein folds as an α -helical dimer (Dokland *et al.*, 2004; Jones *et al.*, 2003; Ma *et al.*, 2004; Shang *et al.*, 2018) exposing a non-polar face predicted to contact the lipids of the internal leaflet of the viral membrane, and a basic face contacting the RNA genome (Fig. 1(B)). The C dimer, which is initially sequestered by lipid droplets while replication takes place (reviewed by (Byk and Gamarnik, 2016)), subsequently binds the newly replicated genomic RNA molecules to form a ribonucleoprotein (RNP) complex. The RNPs do not accumulate in the cell during infection, and their formation appears to be concomitant to particle assembly and budding.

Glycoproteins prM and E are co-translationally translocated into the ER lumen, where they form a prM/E heterodimer. They both feature a β -sheet rich ectodomain: prM has a single globular β -sandwich encompassing the N-terminal half, while E displays a typical class II membrane fusion protein fold (Kielian and Rey, 2006; Modis, 2013), with three characteristic β -sheet rich domains, termed I, II and III (Fig. 1(D)) making roughly the 4/5th of the intact E protein (Fig. 1(A), second panel). In both glycoproteins, the ectodomain is followed by a flexible region termed “stem” that connects to a C-terminal transmembrane (TM) α -helical hairpin. The E stem forms three mostly amphipathic α -helices oriented tangentially and sandwiched between the viral membrane and the E ectodomain layer (Fig. 1). The prM stem adopts mainly an extended conformation followed by an amphipathic α -helix preceding the TM hairpin. A furin cleavage site is present at its junction with the globular “pr” domain (Fig. 1(C)). The prM/E heterodimer accumulates at the luminal side of the ER membrane until the budding of new particles, and multimerizes via lateral interactions that induce the required membrane curvature to make closed particles even in the absence of genomic RNPs (Allison, 1995b). Incorporation of the viral RNA to form complete virions presumably occurs via interactions of the “turn” in the helix-turn-helix of the TM hairpins (thin arrows in Fig. 1(C)) – the only site exposed at the cytosolic side – and C dimers in the genomic RNPs (Tan *et al.*, 2020). Particle assembly and budding, which also requires specific interactions of the prM/E heterodimers with NS1 (Scaturro *et al.*, 2015), results in the accumulation of immature spiky virions in the neutral environment (pH ~7.2) of the ER lumen, forming para-crystalline arrays. Interaction with the KDEL receptor of the host results in their subsequent transport to the cell surface through the TGN (Li *et al.*, 2015).

The Immature Flavivirus Particle

The surface of the immature particles at neutral pH is formed by 180 prM/E protomers making a network of intertwined interactions with overall icosahedral symmetry, as illustrated in Fig. 2(A), center-left panel. Examination of the available structures revealed a set of key interactions made by the TM helical hairpins of prM and E, which associate to make a trimeric α -helical bundle in the membrane (Fig. 3(C)). The resulting (prM/E)₃ trimer of heterodimers has the form of a propeller – referred to as “triskelion” – projecting three blades (Fig. 3(A)). Sixty triskelions make up the particle interacting about the icosahedral axes as outlined in Fig. 3(B). The molecular axis of the triskelion appears derived from an initial 3-fold axis that is distorted by non-equivalent interactions made by its three blades to form the particle, resulting in significant deviation from 3-fold symmetry (Fig. 3(B)). The three blades, termed I5, I3 and I2 by reference to the closest icosahedral symmetry axis (5-fold, 3-fold and 2-fold), are respectively colored with prM/E in cyan/blue, pink/red and yellow/green in Figs. 2 and 3(B). In the particle, each triskelion has the blades of three adjacent ones interacting directly on top of its central TM helical bundle (Fig. 2(A), center-left), forming prominent trimeric spikes. These spikes were the only distinguishable morphological features in the initial low resolution cryo-EM studies (Zhang *et al.*, 2003; Zhang *et al.*, 2007). The interaction between the three blades forming the spike are not 3-fold symmetric: rather, a local dimer axis relates I3 and I2 blades (red and green in the Figures) with about 650 Å² buried surface area (BSA) per blade, in an interaction involving mainly prM (Table 1). The I5 blade leans on this dimer, with a BSA of about 450 Å², with prM contacting only the E moiety of the I3 blade. The buried surface of the I5 blade is mostly the same prM surface involved in the 2-fold interaction between I2 and I3 blades. The overall arrangement results in a lattice with a highly intertwined pattern, in which most of the lateral interactions are made by prM (colored cyan, mauve and yellow in the I5, I3 and I2 blades, respectively, Figs. 2 and 3(B)). Importantly, very recent cryo-EM data showed that prM directs its TM hairpin from the top of the spike directly into the helical bundle underneath, whereas the E TM hairpin is part of three adjacent bundles. This connectivity results in a heterodimer “swapping” with respect to the initial connectivity deduced from lower resolution cryo-EM maps. The implied pattern is now that each triskelion blade has the prM and E TM hairpins making part of different TM helical bundles (F. Coulbaly, Personal communication; PDB:XXXX). This particular organization of the prM TM hairpins results in a highly interconnected lattice, and is likely to be responsible for the reversible transition between the two lattices when going from neutral to acid pH, and vice-versa.

A cryo-EM structure of the immature ZIKV particle to 9 Å resolution showed internal density directly underneath the α -helical bundle of the triskelions (Fig. 3(C) and (D)) (Prasad *et al.*, 2017). The location of this density supports the notion that C dimers in the genomic RNP interact with the cytosolic side of the TM bundles, although there is no clear density to resolve the C protein in the structure. More recently, an asymmetric reconstruction of the immature particle of Kunjin virus (a flavivirus very close to West

Fig. 2 Flavivirus Particle Organization. (A) Immature (left panels) and mature (right panels) flavivirus particles viewed down an icosahedral 2-fold axis. The mature particle is based in the immature lattice at acid pH, with the difference that prM has been cleaved by furin and the pr moiety is shed upon exposure to neutral pH. Three independent immature prM/E (left) or mature M/E (right) protomers make up the icosahedral asymmetric unit, respectively colored cyan/blue, pink/red or yellow/green according to the nearest icosahedral axis (I5, I3 or I2, as described in the text). The central panels display a surface representation, except for one asymmetric unit shown with the protomers in ribbons. The immature particle displays a highly intertwined arrangement, in which each triskelion is centered underneath a spike formed by the blades of three adjacent ones. The central triskelion in turn contributes one blade each of its three adjacent spikes but the prM moiety of each blade connects directly to the TM helical bundle located underneath each spike. We define a “local” (prM/E)₂ dimer (yellow/green and cyan/blue protomers) within which the TM hairpins of prM are swapped (i.e., the pr “head” of prM interacts with domain II of one E polypeptide, and the prM TM hairpin interacts with the TM hairpin of the opposite E polypeptide; see also Fig. 4(D)). This local dimer appears to give rise to the local dimers in the low pH lattice (upon dissociation of the TM helical bundles). This reorganization is illustrated by using the same color-coding in the center-right panel, where the mature particle is shown, whose surface lattice corresponds also to that of the acid pH immature particle. At neutral pH, the pink/red prM/E protomers form rings about the 20 I3 axes of the particle, with a circular connectivity within each ring via the swapped prM TM hairpins. These same protomers are proposed to re-organize into the 30 (prM/E)₂ dimers sitting on the I2 axes in the low pH lattice. The lateral panels show the organization of the “stem” and transmembrane segments. In the left panel, an outline indicates the three prM/E protomers constituting one triskelion, with the prM TM segment swapped into adjacent alpha-helical TM bundles. (B) The outer panels show the prM/E TM helix bundles in the immature (left) and mature (right) particle, with a zoom as inset. In the central inset, only the center of mass (COM) of the TM hairpin of each subunit is represented, color-coded and with big and small spheres respectively indicating their position in the neutral and acid pH lattice. White arrows show the COM displacements of the prM TM in the local dimer defined above; pale red and yellow arrows display alternative possibilities for its displacement to make the icosahedral dimer.

Nile virus), was determined to 19 Å resolution, showing the presence of an RNP core interacting only on one side with the viral membrane (Therkelsen *et al.*, 2018). This eccentricity of the RNP, which explains the lack of well-defined density in the icosahedrally averaged reconstructions, further suggests that its interactions with only a subset of the 60 trimeric α -helical bundles of the particle may be sufficient for its incorporation into a budding particle. Recent evidence has confirmed the interactions of the triskelion TM bundle with the genomic RNP (Tan *et al.*, 2020).

Acid Sensitivity

Flavivirus virions are lipid-enveloped, pH sensitive macromolecular machines tailored to efficiently deliver the viral genome into target cells upon receptor-mediated endocytosis. As such, they are exquisitely sensitive to acid pH, to which they will be exposed twice in the viral cycle: the first-time during transport to the cell surface, upon exposure to the mildly acidic environment (pH ~6.0) of the trans-Golgi network (TGN). The second (and final) exposure to acid pH occurs in the endosome of a different cell, leading to the irreversible disassembly of the particle with concomitant fusion with the endosomal membrane, thereby releasing the genomic RNP into the cytoplasm of a target cell.

The first acid exposure triggers a major reorganization of the immature particle. The surface lattice disassembles as the trimeric α -helical TM bundle of the triskelion comes apart and the blade/blade contacts forming the spikes are broken. The 180 prM/E

Fig. 3 The building block of immature virions. (A) A triskelion shown in side (top) and top view (bottom), with its three "propeller" blades labeled. prM is in green while E is colored according to domains (domains I, II, III, stem and TM hairpin in red, yellow, blue, cyan and violet, respectively, as in the linear diagram of Fig. 1(A), bottom panel). The prM stem and TM hairpin are shown in grey, as they belong to the heterodimers from adjacent triskelions. The E fusion loop (FL) is in orange. A green arrow points to the region of prM connecting to its TM hairpin in an adjacent alpha-helical bundle. The viral membrane is schematically outlined in brown. The bottom view shows that the triskelion deviates substantially from 3-fold symmetry. (B) Potential assembly pathways. At the top right, a single triskelion is shown in surface representation and colored by blades as in Fig. 2. Marine anchor symbols indicate the connections to adjacent triskelions via the prM TM hairpins. The triskelions interact laterally around the 5-fold axes (as shown to the left) and about the 3-fold axes of the particle (as shown to the right). These subsets in turn associate with each other, as shown in the lower panels. In the spikes, the I2 and I3 propeller blades (red and green) make a near 2-fold interaction, as described in the text, while the I5 blade (blue), leans against the I3 blade only, without contacting the I2 blade. These contacts are shown by thin black arrows in the middle panels. Note that full spikes are only formed upon interaction of pentameric triskelion assemblies, forming the spikes outlined in the lower panel. (C) Low resolution internal density map for the immature ZIKV particle (Prasad et al., 2017), showing the density of the TM bundle and membrane proximal region of one triskelion, with density above corresponding to the blades of three adjacent triskelions making a spike (as labeled). The contours were chosen to show continuous density for the lipid headgroup region of the membrane (indicated by the two red arrows). At this contour level, there is internal density (cyan) that can be interpreted as being a C dimer underneath, intercalated by weak density. Internal density attributed to the RNA genome is shown in dark blue. (D) Representation of the TM segments in two icosahedral facets of the immature particle (i.e., 6 asymmetric units) at the level of the membrane. The TM hairpins are shown as ribbons, colored as in Fig. 2, and the gray surfaces correspond to the cyan density in (C) viewed from the outside of the particle. Grey and orange ellipses indicate swapped prM TM segments around the 5-fold and 3-fold axes. Pairs of grey ellipses correspond to the local dimers defined in the legend to Fig. 2. Small black polygons mark the icosahedral symmetry axes of the particle, as a guide.

Table 1 Buried accessible surface areas (BASA) per prM/E blade in the spike

blade	I2	I3	I5	Total
I2-E	/	10.1	0	10.1
I2-pr	/	654.0	0	654.0
total	/	664.1	0	664.1
I3-E	6.8	/	583.8	590.6
I3-pr	641.2	/	74.5	715.7
total	648.0		658.3	1305.3
I5-E	0	141.0	/	141.0
I5-pr	0	390.4	/	390.4
total	0	431.4	/	431.4

Note: BASA were calculated using Areaimol (CCP4) (Lee and Richards, 1971) and Zika immature model 5U4W. The colors correspond to the E moiety in the triskelion blades displayed in Figs. 2 and 3(B). Note that the I5 and I2 blades do not contact each other in the spikes.

Table 2 Protein rearrangements in the viral membrane

E-TM	Δcom (Å)	prM-TM	Δcom (Å)
I5	40	I5	56
I3	39 (64)	I3	48 (83)
I2	44	I2	4

Note: Translation of the E and prM trans-membrane hairpins during the transition from the neutral form to the acid pH immature form of the DENV1 particle. E-TM corresponds to E aa450–495, and M-TM to aa 130–166 of prM. Comparison done using entries PDB:4B03 (immature particle)- and PDB:4CCT (mature particle) (Kostyuchenko *et al.*, 2013). For the I3 protomers, the values correspond to the shift indicated by the pale red arrow in Fig. 2(B). The values in parenthesis correspond to an alternative shift, indicated by the yellow arrow in Fig. 2(B). For the I2 and I5 protomers, the shifts correspond to the white arrows in Fig. 2(B). (these shifts preserve the local dimer).

protomers reorganize into 90 (prM/E)₂ dimers forming a smooth shell completely cloaking the viral membrane (Li *et al.*, 2008; Yu *et al.*, 2008). The TM hairpins forming the trimeric bundle undergo different translations in the membrane, as listed in Table 2. Although the fate of the individual protomers is not established with certainty, the local dimer (prM/E)₂ defined in Fig. 2 suggest a potential pathway for the transition. In this dimer, the E surfaces directed towards each other are the same that form the local dimer in the mature form (Fig. 2(A)). Indeed, as shown in Fig. 4, there is essentially a translation of the prM/E protomers in opposite directions to form the mature-like dimer, allowing the E ectodomains to lie flat on the membrane. As shown for DENV2, this conformational change is reversible, and re-exposure to neutral pH results in dissociation of the (prM/E)₂ dimers of the acid pH lattice (Fig. 4, right panels) and re-formation of the triskelions and the spikes (Yu *et al.*, 2008). The stem regions, tethering the ectodomains to the TM anchor, play a crucial role in controlling the pH dependent reversible conformational changes. Yet the dynamic transitions in both prM and E stems that regulate the drastic functional rearrangement observed are not understood. The particle reorganization is rendered irreversible by furin cleavage (Stadler *et al.*, 1997) of the pr “head” from the stem “tether”, which removes the cross-linking between triskelions. The head remains bound in the resulting (prM/E)₂ dimers of the smooth particle as long as the environment is acidic (Li *et al.*, 2008; Yu *et al.*, 2008). In this way, the release into the neutral pH extracellular milieu after prM cleavage entails no reversion to the spiky form. A concomitant drop in affinity of the pr head for the (M/E)₂ dimer at neutral pH leads to its dissociation and shedding, resulting in a smooth mature virion exposing 90 metastable (M/E)₂ heterodimers at its surface (Fig. 2(A), middle-right panels). The mature particle is primed for fusogenic activation upon subsequent exposure to low pH. In the absence of pr, the second exposure to acid pH triggers an irreversible conformational change of protein E (Allison *et al.*, 1995a; Stiasny *et al.*, 2001), in which it dissociates from the (M/E)₂ dimers (Fig. 1(D)) so that E monomers can insert into the target membrane. The membrane-inserted monomers then re-associate to form E homotrimers (Fig. 1(E)) (Liao *et al.*, 2010; Stiasny *et al.*, 2007; Zheng *et al.*, 2014) that drive the fusion of the viral envelope with the endosomal membrane.

Mature Particle Organization

As discussed above, the mature virion maintains the organization of the immature particle after the acid-induced conformational change. We refer to this arrangement as the “mature” lattice for convenience, as there are no high-resolution structural studies of

Fig. 4 Reorganization of the local (prME)₂ dimer during the transition to the low pH lattice. To highlight the swapping of the prM TM hairpin, one protomer in the dimer is shown in surface representation and the other as ribbons, colored as in Fig. 3(A). The (prME)₂ dimers in the neutral pH (left) and the acid pH (right) lattice are shown with their local 2-fold symmetry axes perpendicular to (top panels) and in the plane of (middle panels) the Figure. In the neutral pH lattice, the two protomers belong to two different triskelions (as labeled). The swapping of the prM TM hairpin is indicated with a black arrow in the side view (note that the E and prM chains displayed in ribbons interact with each other at the top, whereas in the membrane the interaction is between prM in ribbons and E in surface, and vice-versa). The third row shows the front protomer alone to better visualize the swapping, with colored arrows showing the rearrangement of the TM hairpins. Table 2 shows the transformation undergone by the E ectodomain in all three protomers of the triskelion.

the immature lattice at acidic pH. The only available cryo-EM map is at 25 Å resolution (accession EMD5006) (Yu *et al.*, 2008), and at this resolution its organization appears identical to that of mature virions. It is important, however, to recall that furin maturation occurs only after the transition between the two lattices, and that once prM is cleaved, the resulting pr/M/E heterotrimeric protomers are no longer capable of driving the reversible switch to the spiky lattice when exposed to neutral pH.

The organization of the mature flavivirus particle has been thoroughly described (Hasan *et al.*, 2018; Mukhopadhyay *et al.*, 2005). The (M/E)₂ dimers associate by sets of three, making parallel interactions and forming what is called a “raft”, in which a central dimer (in green) is related by an icosahedral 2-fold symmetry axis of the particle, while two symmetrical dimers at each side display only local 2-fold symmetry (blue/red dimers, Fig. 2(A), third panel). Thirty such rafts coat the viral surface to completely cover the viral membrane. The raft arrangement is reminiscent of a tricontahedron – a polyhedron with 532 point-group symmetry and 30 diamond shaped faces normal to the 2-fold icosahedral axes of the particle. Yet the particle is not polyhedral, as the curvature of the individual rafts results in a spherical virion. The glycan chains (one or two per E polypeptide, depending on the flavivirus) project from the smooth surface. Domain III, which has been proposed to be responsible for receptor binding (although there is no direct experimental evidence), protrudes slightly from the smooth particle. The viral membrane, in contrast, was shown to be highly distorted by the short TM α-helical hairpins, and the inner leaflet shows a polygonal shape that contrasts with the spherical outer surface of the virus particle. A 35 Å resolution non-symmetrized cryo-EM reconstruction of the mature particle of Kunjin virus showed that, contrary to immature particles at neutral pH, the density of the internal RNP is not eccentric (Therkelsen *et al.*, 2018). These data are in line with the dissociation of the trimeric α-helical bundles postulated to interact with the RNP core, freeing it to adopt a membrane-equidistant, central location in the particle.

Physical Principles of the Flavivirus Particle Organization

The organization of the flavivirus particle clearly does not follow the quasi-equivalence principle enunciated by Caspar and Klug (Caspar and Klug, 1962). This principle served to explain the organization of multiple viruses, postulating quasi-equivalent

interactions between the viral coat proteins (CPs) at the particle surface to make a closed shell. Although quasi-equivalence accounted for the organization of many spherical viruses, it did not for many others. Yet, a recent generalization of the geometrical concepts of Caspar and Klug (Rochal *et al.*, 2016) allowed its extension to understand the organization of virus particles not obeying the principle of quasi-equivalence. This basic formalism can indeed be adapted to understand the organization of both lattices, at neutral and at acid pH, of the immature flavivirus particle. The Caspar and Klug formulation for building an icosahedral capsid can be described as starting from a two-dimensional (2D) hexagonal lattice in which the individual CPs display identical lateral interactions to make a planar protein shell with P6 symmetry. In such a lattice, the 6-fold axes also generate parallel 3-fold and 2-fold axes, all normal to the lattice plane. Applying the architectural concepts for building a geodesic dome developed first by Walther Bauersfeld and expanded later by Walter Gropius and Buckminster Fuller, Caspar and Klug converted the planar protein shell into an icosahedral coat by eliminating one of the six proteins surrounding a 6-fold axes and rearranging the contacts to make a 5-fold axis instead, as outlined in Fig. 5(A). Each hexagonal node of the lattice is thus transformed into one of the 12 vertices of an icosahedron. This procedure allows the generation of icosahedral particles of increasing size built from similarly sized CPs by leaving intact increasing numbers of 6-fold nodes in between the nodes that are converted into 5-fold axes. The icosahedral lattice generated by the above procedure maintains the 3-fold and 2-fold nodes, but they now intersect with the 5-fold axes at the center of the icosahedron to yield 532 point-group symmetry. Although the interactions made between CPs at the 5-fold axes are not equivalent to those they make at the 6-fold nodes – termed quasi 6-fold (Q6) axes as they are now local – they were termed quasi-equivalent as they involve the same interacting surfaces of the protein. Fig. 5(B) shows that there are other ways of transforming a planar lattice into a spherical lattice with 532 point-group symmetry. In particular, the distortions introduced to the planar lattice in Fig. 5(B) indicate a way of transforming a planar lattice of triskelions in which each subunit displays equivalent interactions, into a spherical lattice in which the interactions are non-equivalent. The resulting pattern, instead of corresponding to a truncated icosahedron, corresponds to a polyhedron termed rhombicosidodecahedron (Twarock and Luque, 2019) that recapitulates all the observed interactions of the neutral pH lattice.

The triangulation number T of the icosahedral lattice was defined by Caspar and Klug as $T = h^2 + k^2 + hk$, i.e., as the square of the distance along the edges of the planar hexagonal lattice of consecutive 6-fold nodes transformed into 5-fold vertices to yield an icosahedral lattice. h and k are thus integers counting the number of Q6 nodes in between adjacent vertices along the two directions of the triangulated sphere (Fig. 6(A)). Lattices in which the vertices are along a single direction (i.e., one of the indices is null, h or $k = 0$, or are along the diagonal, $h = k$), are centrosymmetric, whereas all other combination of indices lead to a chiral lattice. As pointed out by Rochal and collaborators (Rochal *et al.*, 2016), the Q6 nodes are not real nodes of the lattice, yet the Caspar and Klug construction required each individual CP not to occupy these “special” positions. As illustrated in Fig. 6(B), such nodes are not forbidden, and an icosahedral lattice can be constructed by placing CPs over Q6 nodes. The resulting pattern is termed “spherical lattice” (SL).

An illustration of the principles of Rochal *et al.* is provided in Fig. 6. In the basic $T = 28$ l and $T = 19$ d icosahedral lattices, respectively corresponding to the spherical lattices SL<4,2> and SL<3,2> (Fig. 6(A)), the original 6-fold nodes of the planar P6 lattice used to derive it are shown as empty blue circles. The Caspar and Klug formulation allows tiling the lattices by placing a capsid protein only at general positions, thereby accounting for 6 CPs around each Q6 node and five about the I5 vertices, all displaying quasi-equivalent interactions (Fig. 6(B)). The resulting tiling has 60T copies of the CP making a closed particle (i.e., 1680 proteins on the $T = 28$ l lattice, and 1140 in the $T = 19$ d lattice). Positioning instead a CP on the Q6 nodes yields an icosahedral lattice in which four CPs (instead of 28) interact to form a closed particle in the 28 l lattice, and three instead of 19 in the 19 d lattice. The CPs with a unique environment are represented in Fig. 6(C) in different colors and occupy the nodes containing a full CP hexamer in the Caspar and Klug construction (panel B). The flavivirus surface lattice can be understood in terms of the two lattices represented in Fig. 6, the immature particle as a $T = 28$ l lattice in which the yellow position about the 5-fold axes remains vacant, and the mature lattice (or the immature lattice at acid pH) as a fully occupied $T = 19$ d lattice. The organization of the flavivirus envelope proteins on these lattices is indicated with a purple outline in Fig. 6(D), in which each CP is assimilated to a prM/E heterodimeric protomer. In Fig. 6(E), a (prM/E)₃ triskelion is positioned occupying a third of one of the 20 icosahedral facets, while three (M/E)₂ dimers are positioned to cover one of the 30 diamond-like facets of the tricontahedron corresponding to the mature flavivirus particle.

Thermodynamic Transition Between Icosahedral Surface Lattices

In their generalization of the Caspar and Klug geometric model, Rochal and colleagues went a step further, and showed that Landau’s “weak crystallization theory” could be applied to “crystallization” on an icosahedral surface lattice. This theory uses thermodynamic considerations to describe the first order transition from a liquid state to a crystalline state, and can be decomposed in terms of wave vectors (Kats *et al.*, 1993). Rochal and colleagues showed that the 532 point-symmetry group imposes important restrictions to the wave number l such that the spherical harmonics corresponding only to certain l values are not null. They showed that the allowed wave numbers are given by the series $l = 15 + 6i + 10j$, where i and j are integers or zero. The first l values in this series are: $l = (15, 21, 25, 27, 31, 33, 35, \text{etc.})$, each of which leads to a characteristic “irreducible icosahedral density function” representing the weak crystallization energy Δ for the corresponding icosahedral lattice. In particular, Rochal *et al.* showed that the lattices SL<4,2> and SL<3,2> presented in Fig. 6 are characterized by wave numbers $l = 31$ and $l = 25$, respectively. The density function corresponding to these two wave numbers is represented as a function of the angular variables

Fig. 5 Derivation of the icosahedral surface lattice of the immature flavivirus particle. (A) The top panel shows an example of the Caspar and Klug geometrical construction to generate an icosahedral lattice from a planar hexagonal lattice with triangulation $T = 3$ – i.e., with three CPs in the icosahedral asymmetric unit (IAU). Each CP is represented by a rectangle colored differently in the IAU, where they are arranged by groups of three as in a triskelion. A black dot on each rectangle indicates the side where the α -helical TM hairpins cluster. One triskelion is highlighted with a yellow outline, and small yellow triangles mark the blades of three adjacent triskelions that form a spike on top of the highlighted one. Selected nodes of the planar lattice (shown in a pink background) are converted into 5-fold axes, creating a 5-fold vertex. Applied in a regular way – in this case, leaving one 6-fold node (or Q6 axis) in between – this process results in the construction of a symmetrical closed particle. In this case, the Q6 and I3 axes coincide. The resulting closed particle is associated to the truncated icosahedron illustrated in between the two panels – with 20 hexagonal facets normal to the Q6 axes, and 12 pentagonal facets normal to the I5 axes. The I2 axes intersect the edges between hexagonal facets. In the planar lattice, all the interactions between the CPs are equivalent: the 2-fold interactions between green and blue are the same as those between two red ones. In the truncated icosahedron drawn below, only the red CPs maintain strict 2-fold interactions while the green and blue interact about a local 2-fold axis. The interactions between blue/green CP dimers along the I5 pentamer edges are quasi-equivalent to those between red/red and blue/green dimers at the edges of the Q6 hexamers. This lattice corresponds to triangulation $T = 3$, as defined in the legend to Fig. 6. The curved arrows in the top panel show the changes required to reach the arrangement of panel B. (B) Alternative distortions to the planar hexagonal lattice introduced to generate a particle organized as the immature flavivirus virions. In this case, before turning the pink hexagonal facets into pentamers, they are brought out of plane by turning the 6-fold node relating them in the P6 lattice into a 3-fold axis. For this purpose, the pink hexagonal facets are rotated by 30 degrees anticlockwise, breaking the 2-fold inter-vertex contacts between red CPs in the planar lattice and bringing them into forming different inter-vertex contacts relating triskelions about the I3 axes. The required transformation in 3-dimensions is more complex, as it brings out of plane the interactions about I3, I2 and I5 axes. The overall transformation is partially indicated by the curved arrows in panel A. The resulting interactions between CPs become non-equivalent. The triskelions in the planar lattice are postulated to have 3-fold symmetry, while those in the icosahedral lattice deviate from it, as shown in Fig. 3(A). The Archimedean solid associated with the resulting lattice is termed “rhombicosidodecahedron”, illustrated in the inset and in the second panel. It has 12 faces normal to the 5-fold axes (pink), 20 triangular faces normal to the 3-fold axes (yellow), and 30 rhombic faces normal to the 2-fold axes (white). The lower panel displays the immature particle in the same orientation, with the same triskelion highlighted, buried under a spike made from the blades indicated by the yellow triangles in the middle panel. Note that a similar arrangement of the triskelions could be reached using the $T = 3$ lattice as in (A), except that it would leave a large space surrounded by 6 triskelions at the particle’s 3-fold axes, in an arrangement that would contain blue pentamers about the I5 and red/green hexamers about the I3 axes. Also, the triskelions would display quasi-equivalent interactions about the 2-fold axes (red-red, at the edges between hexamers) and quasi 2-fold (blue-green) about the edges between pentamers and hexamers. These interactions are clearly absent in the flavivirus immature particle.

Fig. 6 Triangulation and derivation of spherical lattices. (A) Definition of triangulation and two examples. The top panel shows an icosahedral lattice with $T = 28$ with indices $h = 4$ and $k = 2$ (top panel) and $T = 28$ with $h = 3$ and $k = 2$. The triangulation T number, $T = h^2 + k^2 + hk$, is indicated. Each unit cell in the virtual planar lattice contains 6 CPs, and all CPs are in an equivalent environment. Empty blue circles denote the 6-fold nodes that remain as Q6 axes. The examples show two chiral icosahedral lattices: in the top panel, it is laevo as the indices leading from one vertex to the next are 4 nodes along h and 2 to the left along k . Similarly, in the bottom panel, the lattice is dextro as there are 3 nodes along h followed by 2 to the right along k . The corresponding operations are shown by thin blue arrows in both panels, and the indices are labeled. (B) The geometric model of Caspar and Klug with 6 CPs per unit cell of the virtual planar lattice and 5 around the I5 vertices, making CP hexamers and pentamers via quasi-equivalent interactions. Each CP is represented by an asymmetric shape colored yellow and green (see inset at the top-left), with a green thin end pointing toward the Q6 or I5 axes. One of the 20 facets of the resulting icosahedron is tiled in this way, the IAU being 1/3rd of the facet. In the top panel, the IAU contains 28 CPs organized as 4 full hexamers, one half-hexamer by the I2 axes and one fifth of a pentamer (1 CP) by the I5 axes. In the bottom panel, the IAU contains 19 CPs organized as three full hexamers and one fifth of a pentamer by the I5 axes. (C) The revised Caspar and Klug geometric construction proposed by Rochal and colleagues (Rochal *et al.*, 2016) uses the same considerations to generate an icosahedral lattice, which is defined as a spherical lattice ($SL < h, k >$) corresponding to the same triangulation indices. In the example of this Figure, the lattices are termed $SL < 4, 2 >$ (top) and $SL < 2, 3 >$ (bottom), as labeled. Note that the order of the indices affects the chirality, as $SL < h, k >$ denotes a lattice that is the $SL < k, h >$ enantiomorph. The difference in the new construction is that the individual CPs are placed on the nodes of the planar lattice, except in those nodes that become special positions (for instance, the node coincident with the I2 axes in Fig. 6(C), top panel). The CPs are shown as colored dots on the lattice: there are 4 CPs in the IAU of the $SL < 4, 2 >$ ($N=4$, corresponding to the four full hexamers in B, top panel) and 3 in the $SL < 2, 3 >$ ($N=3$, corresponding to the three full hexamers in B, bottom panel). The special positions, i.e., the nodes coinciding with the I2 axis, occupied by half a hexamer in the Caspar and Klug model, or the I5 axis, are left vacant (panel B). The icosahedrons displayed here are drawn at the same scale, but the one in panel B would be substantially larger, given the number of CPs per facet. Note that the SL construction is equivalent to the Caspar and Klug $T = 4$ icosahedral lattice. Similarly, an $SL < 4, 1 >$, resulting in $N=3$ (not shown in the Figure,) would be equivalent to a $T = 3$ in the Caspar and Klug construction (displayed in Fig. 5(A)). The Caspar and Klug construction and the quasi-equivalence principle thus represent a special case, encompassed by the construction presented by Rochal *et al.* (D) The organization of the flavivirus immature particle corresponds to an $SL < 4, 2 >$ lattice in which one of the allowed positions is vacant (the node around the 5-fold axes, top row), i.e., with $N = 3$. The base of the triskelions in one icosahedral facet is outlined. The mature particle corresponds to the $SL < 2, 3 >$, as noted previously (Rochal *et al.*, 2016). The rectangles drawn on this lattice indicate the (M/E)₂ dimers forming the mature particle (lower panel). (E) Top panel: one (prM/E)₃ triskelion (corresponding to one icosahedral asymmetric unit) displayed in surface representation and placed to scale on the $SL < 4, 2 >$ lattice. Bottom panel: three (M/E)₂ dimers (forming two icosahedral asymmetric units) placed to scale on the $SL < 2, 3 >$ lattice.

on a spherical coordinate system in Fig. 7(A). They correspond to the probability distribution of the CPs “crystallizing” in this lattice. As a guide, we have outlined with a black triangle the location of one triskelion in the $l = 31$ plot, and a magenta rhombic tile comprising the three dimers of a raft in the mature particle in the $l = 25$ plot. The middle top panel shows a superposition of the two plots, with arrows indicating the transitions the CP (in our case, a prM/E protomer) would undergo to switch from the probability maximum in one lattice to that in the other.

Inspection of the immature lattice at neutral pH further suggests an order of events for the transition to the low pH lattice, in particular because the blades of the I3 protomers are trapped in the spike in between the I2 (green/yellow) and I5 (blue/cyan) blades (Table 1) of the local dimer (Fig. 7), which need to come apart for the transition to proceed. As the contacts in this lattice become destabilized by protonation, the local dimer can re-organize as indicated in Fig. 4 to reach an alternative energy minimum illustrated by the different pattern of the probability distribution displayed in Fig. 7(A). The I3 blades (red/pink) are left to rearrange around the icosahedral 2-fold axes to form the icosahedral dimers of the acid pH lattice. The overall shift is circular: the I5 protomers (cyan/blue) become I3, the I2 ones (yellow/green) become I5, and the I3 (pink/red) become I2, as shown by the permutation of colors around the icosahedral axes in Fig. 7B, left compared to right.

Fig. 7 Thermodynamics of the low pH-induced lattice transition. (A) Plot of the icosahedral density functions $\Delta\rho(\theta, \varphi)$ for wave numbers $l = 31$ (left) and $l = 25$ (right), respectively superposed to the matching $SL\langle 4,2\rangle$ and $SL\langle 2,3\rangle$ lattices. A mesh shows the probability distribution of protomers in the lattice, and dots indicate the highest peaks. In the left panel, a deltoidal green outline indicates the asymmetric unit of the neutral pH lattice (an "E" labels the peak corresponding to the position left empty in the lattice (see Fig. 6(C)-(D))). In the right panel, a magenta diamond shape outlines two asymmetric units about the I_2 axis, matching the rafts of the mature flavivirus particles. (B) The left and right panels show the immature particle at neutral pH and at acid pH, respectively, with the protomers shown in surface representation and colored as in Fig. 2. The asymmetric units are outlined as in A. (C) Polyhedra matching the icosahedral organization of the immature lattice at neutral pH (left) and at acid pH (right). Note the deltoidal and rhombic faces matching the arrangements shown in A and B. The deltoidal hexecontahedron is the dual of the rhombicosidodecahedron drawn in Fig. 5(B). (Two polyhedra are dual when the faces of one correspond to the vertices of the other, and vice versa).

Discussion

Despite remarkable progress in understanding the structural organization of the flavivirus particles achieved in the past few decades, multiple questions remain unanswered. Understanding in detail the conformational change undergone by the immature particle upon exposure to acid pH remains a major challenge. The identified close relation between the two corresponding icosahedral lattices provides new clues as it suggests that upon protonation, the destabilization of the contacts made a neutral pH puts each prM/E protomer down the slope to reach a lowest energy location – corresponding to a maximum in the order parameter density function plotted in Fig. 7 to make the required contacts in the alternative lattice. And vice versa when the pH is raised again in the absence of furin cleavage. The fact that the initial SL<4,2> lattice leaves one position vacant likely facilitates the transition from one lattice to the other by avoiding potential steric interference between protomers.

In summary, the flavivirus exit pathway involves a fascinating set of macromolecular interactions which are not understood today. We hope that this review will have helped bring up the relevant questions to be addressed in the years to come. The advent of correlative light and electron microscopy, allowing the visualization of complex processes within cells, will be key to provide further insight into these complex macromolecular processes.

Acknowledgement

We thank Dr. J. Navaza for helpful discussions and providing bioinformatic tools, and Dr. F. Coulibaly for sharing unpublished data.

Introduction

The double-stranded RNA (dsRNA) viruses are non-enveloped icosahedral viruses with multiple concentric icosahedral capsid layers. These viruses are classified into twelve families displaying a wide host range, including bacteria, fungi, plants, animals, and humans. The *Reoviridae* represent the largest and most diverse dsRNA virus family. Based on the structural organizations of the viral particles, members of the *Reoviridae* are grouped into two subfamilies, the non-turreted *Sedoreovirinae* and the turreted *Spinareovirinae*. The members of *Sedoreovirinae* have a smooth outermost layer short viral spikes and includes six genera (*Cardoreovirus*, *Mimoreovirus*, *Orbivirus*, *Phytoreovirus*, *Rotavirus*, and *Seadornavirus*). The characteristic feature of the members of *Spinareovirinae* is that they have large turreted structures at the 5-fold axes of the icosahedral particles. This subfamily consists of nine genera (*Aquareovirus*, *Coltivirus*, *Cypovirus*, *Dinovernavirus*, *Fijivirus*, *Idnoreovirus*, *Mycoreovirus*, *Orthoreovirus*, and *Oryzavirus*) (Dermody, 2013). Structures of many dsRNA viruses have been determined by X-ray crystallography and/or cryo-electron microscopy (cryo-EM) techniques, providing molecular insights into their assembly and replication mechanisms. Here, we review the similar and contrasting structural characteristics of dsRNA viruses with a focus on the members of the *Reoviridae*, including some novel features that are revealed by recent asymmetric analysis using cryo-EM.

Overall Structure of the *Reoviridae* Family Viruses

The Non-Turreted Subfamily *Sedoreovirinae*

Rotavirus

Rotavirus, the leading cause of diarrheal diseases in animals and young children worldwide, is a large icosahedral virus with a diameter of ~100 nm (Fig. 1(A)). The rotavirus genome is composed of 11 dsRNA segments encoding six viral structural proteins (VP1–VP4, VP6–VP7) (Table 1) and six non-structural proteins (NSP1–NSP6) (Estes, 2013). The VPs form three concentric capsid layers, while the NSPs are not present in the mature viral particles yet are critical for virus replication. The outermost layer that is composed of glycosylated capsid protein VP7 and the middle layer composed of VP6 both assemble with $T = 13$ (*laevo*) icosahedral symmetry (Prasad *et al.*, 1988). The protease-sensitive spike protein VP4 spans the VP7 and VP6 capsid layers and protrudes from the virion surface. The VP7 and VP4 proteins define the G- and P-genotypes of rotaviruses, respectively. The innermost capsid layer is formed by 120 copies of VP2 and exhibits $T = 1$ icosahedral symmetry (Prasad *et al.*, 1996; Li *et al.*, 2009; McClain *et al.*, 2010; Estrozi *et al.*, 2013; Settembre *et al.*, 2011) (Fig. 2(A)). The RNA-dependent RNA polymerase (RdRp) VP1 and the capping enzyme VP3 form a heterodimer that is anchored near the 5-fold vertices beneath the VP2 core layer.

Orbivirus

Bluetongue virus (BTV), the prototype member of the genus *Orbivirus*, is an important insect vectored pathogen of wild ruminants and livestock that causes significant economic losses in many counties (Roy, 2013). BTV has a genome of 10 dsRNA segments, which encodes seven structural proteins (VP1–VP7) (Table 1) and four non-structural proteins (NS1, NS2, NS3, and NS3A). The overall organization of the virion that is 90 nm in diameter with three capsid layers is similar to that of rotavirus except for the outer capsid layer (Fig. 1(B)). The outer capsid layer is formed by trimers of VP2 and VP5 interdigitating with one another; the middle layer that is similar to the rotavirus VP6 layer contains VP7 trimers; the innermost core layer constitutes 120 subunits of the capsid protein VP3 with the RdRp VP1, the mRNA capping enzyme VP4, and the putative helicase VP6 attached at the inner surface of VP3 (Stauber *et al.*, 1997; Sutton *et al.*, 2007; Roy, 2017; Zhang *et al.*, 2016; Grimes *et al.*, 1998; Nason *et al.*, 2004; He *et al.*, 2019).

Phytoreovirus

Rice dwarf virus (RDV) is a plant virus of the genus *Phytoreovirus* and causes rice dwarf disease that reduces crop production resulting in economic loss in Asia. The viral genome consists of 12 dsRNA segments encoding seven structural (P1, P2, P3, P5, P7, P8, and P9) (Table 1) and five non-structural (Pns4, Pns6, Pns10, Pns11, and Pns12) proteins (Nakagawa *et al.*, 2018). In contrast to rotavirus and orbivirus, the RDV particles are slightly smaller, with ~70 nm in diameter (Fig. 1(C)) and contain a double-layered capsid shell (Lu *et al.*, 1998). The outer shell is formed by the major protein P8 and the minor proteins P2 and P9. There are 780 copies of the P8 protein, which as 260 trimers, follow the $T = 13$ icosahedral symmetric organization (Fig. 2(B)). The inner shell, similar to VP2 and VP3 capsid layers in rotavirus and orbivirus, respectively, is composed of 120 molecules of P3, the RdRp P1, the capping enzyme P5, and the nucleic acid-binding protein P7. The 3.5 Å crystal structure of an RDV particle has provided the structural details of the capsid proteins (Nakagawa *et al.*, 2003).

Fig. 1 Structures of dsRNA viruses. The surface representation of each dsRNA virus was viewed along a 5-fold axis, as indicated by the black pentagon symbol. The viruses are radially colored using rainbow colors, from red to blue (25–45 nm), with a cutaway view shown below to reveal the internal density of the virus. Table 1 Structural proteins of selected reoviruses

Capsid layer	Non-turreted <i>Sedoreovirinae</i>			Turreted <i>Spinareovirinae</i>		
	<i>Rotavirus</i>	<i>Bluetongue virus</i>	<i>Rice dwarf virus</i>	<i>Mammalian orthoreovirus</i>	<i>Aquareovirus</i>	<i>Cypovirus</i>
Outer	VP4 spike	VP2 spike		Attachment protein $\sigma 1$		
	Major capsid protein VP7	Major capsid protein VP5	Major capsid protein P8 and minor capsid proteins P2 and P9	Major capsid proteins $\sigma 3$ and $\mu 1$	Major capsid proteins VP7 and VP5	
Middle	Major capsid protein VP6	Major capsid protein VP7				
Core	Major capsid protein VP2	Major capsid protein VP3	Major capsid protein P3	Major capsid proteins $\lambda 1$ and $\sigma 2$	Major capsid protein VP3 and VP6 clamp	Major capsid protein VP1
	RdRp VP1	RdRp VP1	RdRp P1	RdRp $\lambda 3$ and its cofactor $\mu 2$	RdRp VP2 and its cofactor VP4	RdRp VP2 and NTPase VP4
	RNA capping enzyme VP3	RNA capping enzyme VP4 and the helicase VP6	RNA capping enzyme P5 and RNA binding protein P7	RNA capping/ turret $\lambda 2$	RNA capping/ turret VP1	RNA capping/ turret VP3 and VP5 clamp

Fig. 2 The structural organization of non-turreted and turreted dsRNA viruses. (A) The triple-layered particle of rotavirus (PDB 4V7Q). The outer capsid protein VP4 and VP7 are colored in red and yellow, respectively. The VP6 protein of the middle layer is in light blue. The VP2A and VP2B of the core layer are shown in light green and forest green, respectively. (B) The double-layered particle of RDV (PDB 1UF2). The core layer protein P3 and the outer layer protein P8 are colored in green and light blue, respectively. A fragment of nucleic acid-binding protein P7 is shown in magenta. (C) Reovirus T1L (PDB 2CSE) (Zhang *et al.*, 2005). The viral proteins are labeled in a cutaway view on the right of the panel. (D) Single-layered cytoplasmic polyhedrosis virus (CPV) (PDB 3JAY). The pentamer of turret protein VP3 is colored in pink. The conformer of the core-shell protein VP1A and VP2B are colored in light green and forest green, respectively. The clamp protein VP5 is in light blue.

The Turreted Subfamily *Spinareovirinae*

Orthoreovirus

Mammalian orthoreovirus (reovirus) infects a variety of mammals, including humans. It has been linked to celiac disease and used as an oncolytic virus (Tenorio *et al.*, 2019; Dermody, 2013). The reovirus genome consists of 10 dsRNA segments: three large (L1–L3), three medium (M1–M3), and four small (S1–S4) segments, encoding lambda (λ), mu (μ), and sigma (σ) proteins, respectively (Dermody, 2013). There are twelve reovirus proteins, including the eight structural proteins ($\lambda 1$, $\lambda 2$, $\lambda 3$, $\mu 1$, $\mu 2$, $\sigma 1$, $\sigma 2$, and $\sigma 3$)

(Table 1) and four non-structural proteins (μ NS, μ NSC, σ 1s, and σ NS). The virus particles are ~ 85 nm in diameter and consist of two capsid layers, an outer capsid layer and an inner core (Fig. 1(D)). The outer capsid layer with a quasi $T = 13$ icosahedral symmetry consists of the membrane-penetration μ 1 protein and its protective cap σ 3 assembled as μ 1 $_3\sigma$ 3 $_3$ heterohexamers (Liemann *et al.*, 2002). The capping enzyme λ 2 forms a pentameric turret at the icosahedral vertices of the reovirus particle that spans through both the inner core and the outer capsid (Fig. 2(C)). Extending from a λ 2 turret at each vertex of the virion is a trimer of the cellular attachment protein σ 1. The reovirus core is ~ 70 nm in diameter and formed by five of the eight viral proteins of the virion: λ 1, λ 2, λ 3, σ 2, and μ 2. The shell contains λ 1 dimers and σ 2 monomers (Reinisch *et al.*, 2000). Minor core proteins, the RdRp λ 3 and its cofactor μ 2, are attached on the inner surface of the core shell around the icosahedral 5-fold vertex.

Aquareovirus

Grass carp reovirus (GCRV), a member of the genus *Aquareovirus* (ARV), causes hemorrhagic diseases in grass carp (*Ctenopharyngodon idella*), resulting in significant economic loss in the aquaculture industry. The genome of ARV contains 11 dsRNA segments that code for seven structural proteins (VP1–VP7) (Table 1) and five non-structural proteins (NSP1–NSP5). The structure of ARV is remarkably similar to that of orthoreovirus with an overall diameter of ~ 75 nm (Fig. 1(E)). The outermost layer is formed by heterodimers of the membrane penetration protein VP5 and the protection cap protein VP7 with an incomplete icosahedral $T = 13$ symmetry. Twelve pentameric VP1 turrets are located at the 5-fold vertices. The core shell is composed of 120 VP3 subunits, which are arranged with $T = 1$ icosahedral symmetry and are clamped together by 120 VP6 monomers. The RdRp VP2 and its cofactor NTPase VP4 associate with each other and within capsid vertices (Cheng *et al.*, 2010; Zhang *et al.*, 2010b; Ding *et al.*, 2018; Wang *et al.*, 2018).

Cypovirus

Cytoplasmic polyhedrosis virus (CPV), or cypovirus for short, has 10 dsRNA segments which encode 10–12 proteins. Unlike other viruses in the *Reoviridae*, which have 2 or 3 capsid layers, CPV with a diameter of ~ 65 nm has a single capsid shell, which makes it a simplified model for the dsRNA viruses (Fig. 1(F)). The structure of CPV has been extensively studied (Hill *et al.*, 1999; Cheng *et al.*, 2011; Yang *et al.*, 2012; Liu and Cheng, 2015; Zhang *et al.*, 2015; Li *et al.*, 2017; Cui *et al.*, 2019). The virus particle contains three major capsid proteins VP1, VP3, and VP5 (Table 1). VP1 forms the capsid shell; VP3 is the capping enzyme; VP5 forms clamps that stabilize the virus capsid, and it also has RNA chaperone-like activity that destabilizes RNA helices and promotes strand annealing in an ATP-independent manner (Yang *et al.*, 2014) (Fig. 2(D)). A transcriptional enzyme complex (TEC) is located at the inner surface of the capsid at the 5-fold axes and consists of two extensively interacting subunits: the RdRp VP2 and the NTPase VP4 (Hill *et al.*, 1999; Zhang *et al.*, 2015).

General Features of the Viral Genome

The genomes of dsRNA viruses generally contain multiple segments except for the members in the *Totiviridae* (e.g., L-A virus), which have a single segment enclosed within the virus core. Members of the *Reoviridae* contain a genome of 9–12 dsRNA segments that are generally monocistronic with each segment encoding one viral protein. However, some segments have additional in-frame initiation codons resulting in the expression of additional viral proteins. The gene segments are packaged in equimolar proportions and vary in length. For example, in rotavirus, the lengths of 11 dsRNA segments range from 0.7–3.3 kb. The positive-stranded (+)RNA of the dsRNA genome and the messenger RNA (mRNA) have a 5'-end cap and a non-polyadenylated 3'-end tail, and the negative-stranded (–)RNA has a diphosphate at its 5'-end. All gene segments have a conserved short 5'- and 3'-end untranslated regions (UTRs), which are important in gene transcription, assortment, and packaging.

Using icosahedral averaging methods, cryo-EM structural studies have shown that a significant portion of the viral genome is ordered and forms concentric layers of density in rotavirus (Prasad *et al.*, 1996; Pesavento *et al.*, 2001), BTV (Gouet *et al.*, 1999), and orthoreovirus cores (Reinisch *et al.*, 2000). More recently, in rotavirus, spherically averaged density shows 8 concentric layers of the dsRNA genome with an average spacing of 28 Å between the layers (Jenni *et al.*, 2019). Pesavento *et al.* observed that the genome of rotavirus could undergo pH-dependent reversible compaction, and their studies suggested that each gene segment is spooled around a transcriptional enzyme complex at the 5-fold vertices such that the segments can be transcribed simultaneously. By contrast, recent cryo-EM using asymmetry reconstruction analyses of CPV and aquareovirus particles revealed that the non-spooled RNA genome forms a liquid-crystalline array within the virus (Liu and Cheng, 2015; Zhang *et al.*, 2015; Wang *et al.*, 2018). With anticipated further technical advances in cryo-EM, future structural studies will likely reveal higher-resolution asymmetric features of the dsRNA genome in other dsRNA viruses.

Structural Organization of the Capsid Layers

The Outer Capsid Layer

Consistent with differing host specificities, the overall structural organization of the outer capsid layer in the *Reoviridae* members show marked variations. In rotavirus, the outermost layer consists of 260 VP7 trimers assembled on a $T = 13$ icosahedral lattice capping the layer below formed by VP6 trimers following the same icosahedral symmetry in such a way that there are solvent channels at all the icosahedral 5-fold and quasi 6-fold axes (Prasad *et al.*, 1988). Another component of the outermost layer is the 60 spikes of VP4 trimers, which are locked in place by VP7 and the VP6 trimers at the quasi 6-fold axes (Fig. 2(A)) (Li *et al.*, 2009;

Settembre *et al.*, 2011). VP7 and VP4 are the main targets for neutralizing antibodies (Prasad *et al.*, 1990; Shaw *et al.*, 1993). The crystal structure of rotavirus VP7 in complex with a Fab of a neutralizing antibody (mAb 4F8) showed how the neutralizing 4F8 Fab stabilizes the VP7 trimers and revealed two Ca^{2+} binding sites at the VP7 inter-subunit contacts (Aoki *et al.*, 2009). The core of rotavirus VP7 folds into two domains, a “Rossmann fold” (domain I) and a jellyroll β sandwich (domain II). The cryo-EM structure of the rotavirus particle showed VP7 uses its the N-terminal arm ($\sim$ residues 51–70) to clamp into the VP6 trimer of the middle capsid layer. It has been proposed that VP7 might bind to $\alpha\beta 2$ integrins using its integrin-binding motif (GPR, residues 253–255). In BTV, the organization of the outer layer, composed of 60 triskelion-shaped VP2 trimers and 120 globular VP5 trimers, is not based on $T = 13$ icosahedral symmetry, and is noticeably different from that of the rotavirus (Zhang *et al.*, 2016).

In turreted reovirus, the outer capsid protein $\mu 1$ and its protective cap $\sigma 3$ form $\mu 1_3\sigma 3_3$ heterohexamers, with three $\sigma 3$ monomers bound on the upper half of $\mu 1$ trimer (Liemann *et al.*, 2002). These heterohexamers are organized with quasi $T = 13$ symmetry because the pentameric $\lambda 2$ turret substitutes the lattice around each of the twelve icosahedral 5-fold axes (Fig. 2(C)). The cellular attachment protein $\sigma 1$ exists as filamentous trimers and extends from a $\lambda 2$ turret at each vertex of the virion (Chappell *et al.*, 2002). Due to the flexibility of $\sigma 1$, only limited densities attributable to the base of $\sigma 1$ trimer have been observed in the cryo-EM map of the virion (Zhang *et al.*, 2005). Among the *Reoviridae*, CPV, with a single capsid layer, exhibits the simplest $T = 1$ structural organization with pronounced turrets at the 5-fold vertices.

Cell Entry of the dsRNA Viruses

The outer capsid proteins initiate the virus infections by recognizing and attaching to specific cellular receptors on the host cell surface (Fig. 3). For instance, the outer capsid proteins, rotavirus VP4, BTV VP2, and orthoreovirus $\sigma 1$ recognize specific cellular receptors, thereby mediating the host specificity, tissue tropism, and pathogenesis of the viruses. These proteins are usually the least conserved structural proteins in the dsRNA viruses and might have evolved to provide distinct mechanisms to recognize specific receptors of different hosts and tissues. Recent structural studies have furthered our understanding of the molecular mechanisms by which the capsid proteins bind to host receptors.

In non-turreted dsRNA viruses, such as rotavirus, the spike protein VP4 is cleaved into VP8* and VP5* domains, which remain associated with the virions. Proteolytic cleavage, which stabilizes the spike into a ‘dimer-looking’ state with a significant portion of one of the subunits in the trimer disordered, is known to enhance the virus infectivity (Crawford *et al.*, 2001; Pesavento *et al.*, 2006). The “root” of VP5* along with a portion of the N-terminal region of VP8* is anchored into the middle capsid layer composed by VP6, while the major portion of VP8* is distally located at the tip of the VP4 spike (Fig. 4(A)). The structure of VP8* has a conserved characteristic

Fig. 3 The replication cycles of rotavirus (A) and reovirus (B). (A) Rotavirus attach to the host cell surface and get internalized into cells via endocytic pathways. The low Ca^{2+} level in the endosome triggers the loss of the outer capsid proteins and release of the transcriptionally active double-layered particles into the cytoplasm. The mRNA transcripts are used for viral protein translation and as template for negative strand RNA synthesis in the viroplasm. The dsRNA genome of rotavirus is assorted and packaged into DLPs, which bud into ER for TLP assembly. The progeny TLPs are released from host cells via cell lysis or by a Golgi-dependent non-classical vesicular transport mechanism. (B) Reovirus enters host cells through receptor-mediated endocytosis. The outer capsid layer is cleaved by host cell proteases in the endosomes, releasing the transcriptionally active cores into the cytoplasm. The newly transcribed mRNAs are used to viral protein synthesis and as templates for negative strand RNA synthesis in the viral inclusions (VIs). The dsRNA genome is packed into viral cores, followed by addition of outer-capsid proteins to form mature progeny viral particles. The cartoon of capped mRNAs and reovirus attachment protein $\sigma 1$ were drawn at the 5-fold axis of the viral particles. A schematic of viral protein translation processes is shown.

Fig. 4 Structure of cell attachment protein of dsRNA viruses in complex with its receptors. (A) Ribbon representation of rotavirus spike protein VP4 (PDB 4V7Q) that is composed of VP8* and VP5* domains. (B) Structures of VP8* proteins in complex with sialo-glycan or HBGA. The VP4 genotypes and the bound glycans are labeled: ARV P³ VP8*/Sia (PDB 1KQR); HRV P⁴ VP8*/H-type 1 pentasaccharide (PDB 5VX5); HRV P¹¹/Type-1 precursor (PDB 4YFZ); HRV P¹⁴/A-type HBGA trisaccharide (PDB 4DRV). The protein and the glycan are shown in ribbon representation and ball-and-stick models, respectively. (C) Structural overlay of reovirus attachment protein $\sigma 1$ in complex with receptors. The glycan receptor binding site on the head and body domains are noted by magenta and gray box, respectively. (D) The structure of reovirus T1L $\sigma 1$ in complex with the GM2 glycan (PDB 4GU3). (E) The structure of reovirus T3D $\sigma 1$ in complex with α -2,3-sialyllactose (PDB 3S6X). (F) The structure of reovirus T3D $\sigma 1$ in complex with JAM-A (PDB 3EOY). The $\sigma 1$ trimer (green, cyan, and blue) and JAM-A (red) are shown in ribbon representation.

galactin-like fold with two twisted β -sheets separated by a shallow cleft. Rotaviruses VP8* recognizes cellular glycans, including sialic acid (Sia) (Dormitzer *et al.*, 2002) and histo-blood group antigens (HBGAs) (Hu *et al.*, 2018, 2015, 2012a). HBGA are genetically determined glycans present on epithelial cells, red blood cells, and in mucosal secretions. The VP8* domain of VP4 spike recognizes cellular glycans in a VP4 genotype (P genotype)-dependent manner to mediate the initial cellular attachment (Fig. 4(B)). Following cell attachment, during the cell entry process, VP4 spike, particularly VP5*, is suggested to undergo drastic membrane-coupled conformational changes to permeabilize host cells (Yoder *et al.*, 2009; Trask *et al.*, 2010; Pesavento *et al.*, 2001). The outer capsid VP7 is a Ca^{2+} -stabilized protein with two Ca^{2+} ion binding sites at each subunit interface of VP7 trimers (Aoki *et al.*, 2009). The loss of Ca^{2+} inside the host cell triggers the dissociation of VP4 and VP7 and the release of DLPs into the cytosol (Salgado *et al.*, 2018). In BTV, the VP2 trimer with identifiable sialic acid-binding pockets is suggested to play a role in cell attachment and receptor engagement, whereas VP5 with distinct α -helical regions is implicated in membrane fusion activity (Forzan *et al.*, 2007; Zhang *et al.*, 2010a). Distinct zinc-binding sites in VP2 and a cluster of histidine residues in VP5 are suggested to control pH-dependent conformational changes required for cell entry of BTV and the subsequent detachment of the outer layer (Zhang *et al.*, 2016).

In turreted reovirus, two outer layer proteins, the filamentous cell attachment protein $\sigma 1$ and the membrane-penetration protein $\mu 1$, are critical for viral entry. The trimers of $\sigma 1$ protrude out from the virus surface from the $\lambda 2$ turret at each vertex of the virion. $\sigma 1$ attaches to cell-surface glycans containing Sia and the immunoglobulin superfamily member junctional adhesion molecule-A (JAM-A). The $\sigma 1$ protein is composed of three domains, including a globular head domain comprised of eight antiparallel β -strands (residues 310–455), a body domain of β -spiral repeats (residues 170–309), and a tail domain (residues 1–160) that has a α coiled-coil (Fig. 4(C)) (Dietrich *et al.*, 2018). The type-1 Lang (T1L) and type-3 Dearing (T3D) orthoreovirus

bind to sialo-glycans using the head domain and the body domain, respectively (Fig. 4(D) and (E)) (Reiss *et al.*, 2012; Reiter *et al.*, 2011). After attachment to the cellular glycans, all human reoviruses bind to the tight junction component JAM-A (Fig. 4(F)) (Kirchner *et al.*, 2008). After initial attachment, the viruses are internalized through binding of $\beta 1$ integrins to reovirus protein $\lambda 2$, which contains integrin-binding motifs, RGD and KGE. The chaperone protein $\sigma 3$ is then removed in cathepsin proteases in the endosome, resulting in the formation of the infectious subviral particle (ISVP). The membrane-penetration protein $\mu 1$ is also proteolytically processed and undergoes conformational changes to rupture the endosomal membrane and release the transcriptionally active virus core into the cytosol (Danthi *et al.*, 2010, 2013).

The dsRNA Virus Core and Endogenous Transcription

A distinguishing feature of the dsRNA viruses in general and of *Reoviridae* in particular is the process of endogenous transcription (Fig. 3). In this process, the genomic dsRNA segments are transcribed within the particle interior and the transcripts are extruded. This process is typically activated by the removal of the outer capsid layer during the entry process (Fig. 3). For instance, the outer layer of rotavirus is removed, resulting in a double-layered particle (DLP) (Fig. 3(A)). The outer layer of DLP is a $T = 13$ icosahedral lattice of 260 VP6 trimers, which are anchored on the $T = 1$ innermost core layer of VP2 (Fig. 5(A)). When incubated with NTPs, Mg^{2+} , and S-adenosylmethionine (SAM), the rotavirus DLPs undergo rounds of transcription, with the mRNA transcripts emerging from the pores/channels at the 5-fold vertices of DLPs (Lawton *et al.*, 1997). The process of transcription is very similar in the case of BTV with the removal of the outer layer consisting of VP2 and VP5, the core particle (the equivalent of rotavirus DLP) with a $T = 13$ VP7 and $T = 1$ VP3 capsid layers is the transcriptionally active form. Similarly, in orthoreovirus, endogenous transcription is activated upon the removal of the outer capsid layer, and the nascent mRNA transcripts exit through the turrets at the 5-fold axes of the resulting infectious subviral particles (Figs. 3(B) and 5(B)).

Viral Innermost Capsid Layer That Encloses the Genome

The innermost capsid layer has a $T = 1$ (also referred to as " $T = 2$ ") icosahedral symmetry with 60 asymmetric dimers and encloses the dsRNA genome (McClain *et al.*, 2010). This structural organization is highly conserved in all dsRNA viruses, including those of bacterial and fungal origins (Luque *et al.*, 2018). X-ray crystallographic and cryo-EM structures of the dsRNA virus cores showed that the innermost capsid proteins share a conserved α -helical domain even despite little sequence identity (Fig. 5(C)). The VP1 of CPV exhibits a slight variation with the addition of a small domain that protrudes from the outer capsid surface. It has been hypothesized that such a conserved organization of the innermost layer has evolved to facilitate and regulate the endogenous transcription by appropriately packing the segmented dsRNA genome and anchoring the RdRp and/or capping enzyme in the interior (Prasad and Privilege, 2003).

Cryo-EM studies of several members of *Reoviridae*, including rotavirus, bluetongue virus, and orthoreovirus, have provided molecular insight into how the unique organization of the innermost layer supports the fascinating process of endogenous transcription. In rotavirus, two VP2 conformers, VP2-A and VP2-B, assembled around the fivefold axis to form a decamer, and 12 of VP2 decamers pack together to form the innermost layer (Fig. 5(C)). Rotavirus VP2 contains the N-terminal tether domain (residues 1–125) and the C-terminal scaffold domain (McClain *et al.*, 2010). The N-terminal domain is flexible. There was no density structurally resolved for the first 99 residues of the VP2-A and the first 80 residues of the VP2-B in the 3.8 Å crystal structure of the inner capsid particle. N-terminal deletion of the VP2 mutant failed to encapsidate VP1 and VP3 into the virus-like particles in vitro (Zeng *et al.*, 1998; Estrozi *et al.*, 2013). Thus, it has been thought that the N-terminal domain tethers the VP1/VP3 complex at the fivefold vertices. The recent in situ cryo-EM structure of rotavirus VP1 revealed that it binds to the inner surface of the VP2 shell with complementary interactions and with three N-terminal arms of VP2, which form a tentacle-like structure (Fig. 6(A)) (Jenni *et al.*, 2019). A similar structural organization of the inner shells has also been observed in other members of the *Reoviridae* family. For instance, in BTV, the RdRp VP1 is anchored inside the core capsid shell via five asymmetrically arranged N termini of the capsid shell protein VP3A around the fivefold axis (He *et al.*, 2019). In ARV, the transcriptional enzyme complex of RdRp VP2 and its cofactor protein VP4 is anchored via four of the five N-termini of the core capsid protein at the fivefold vertices (Wang *et al.*, 2018) (Fig. 6(B)).

Viral RNA-Dependent RNA Polymerase (RdRp)

Due to the lack of cellular enzymes that can synthesize mRNA transcripts using the (–)RNA strand of the dsRNA genome as the template, the dsRNA viruses encode their own viral RdRps and capping enzymes that carry out the endogenous transcription of the dsRNA segments. During the process of endogenous transcription, the virus core remains structurally intact, such that the dsRNA genome is protected from triggering the activation of cellular antiviral interferon responses by dsRNA. In several viruses of the *Reoviridae* family, the RdRp is directly anchored to capsid protein at the inner surface at the fivefold vertices. Crystal structures of the *Reoviridae* RdRps, such as reovirus λ 3 and rotavirus VP1 in isolation have been determined (Tao *et al.*, 2002; Lu *et al.*, 2008). The RdRps are largely structurally conserved with a cage-like organization that includes an N-terminal domain, a right-hand polymerase domain, and a C-terminal “bracelet” domain (Fig. 6(A) and (B)). There are four tunnels in the RdRp for template entry, NTP entry, dsRNA/(–)RNA exit, and mRNA exit. The mRNA cap-binding site is located on the surface of RdRps and has been thought to anchor the 5′-end of (+)RNA, which will guide 3′-end of (–)RNA to re-enter the RdRp for another round of transcription (Fig. 6(J) and (K)).

Recent advances in cryo-EM and single-particle analysis, especially in using focused classification and asymmetric reconstructions, have provided in situ structures of RdRp inside the rotavirus, BTV, ARV, and CPV (Wang *et al.*, 2018; Ding *et al.*, 2018; He *et al.*, 2019; Cui *et al.*, 2019; Ding *et al.*, 2019; Jenni *et al.*, 2019). These structures reveal the conformational changes of RdRp upon transcription and the trajectories of mRNA transcripts. In rotavirus, Jenni *et al.* showed that dissociation of the outer layer of rotavirus leads to RNA synthesis without introducing structural changes in VP1. However, the addition of NTPs, Mg^{2+} , and S-adenosylmethionine to trigger transcription results in significant conformational changes in VP1 and capsid shell protein in DLPs (Jenni *et al.*, 2019) (Fig. 6(A)). These studies have also shown that VP1 attaches to the VP2 shell stochastically at one of the five possible positions at each of the fivefold vertices. In the turreted ARV, the RdRp protein VP2 forms a complex with its cofactor VP4 and genomic RNA near the 5-fold axes (Fig. 6(B)). The in situ cryo-EM structures of CPV RdRp with its associated RNA have revealed the transcription steps by capturing the quiescent, initiation, early elongation, elongation, and abortive states under different conditions (Cui *et al.*, 2019).

Viral RNA Capping

The 5′-cap of mRNA is critical for RNA stability, gene translation, and immune evasion. This cap not only prevents RNA degradation by cellular exonucleases but also promotes RNA translation by specific recognition of the eukaryotic translation initiation factor 4E (eIF4E). Moreover, it is crucial for evading host innate immune response mediated by RIG-I, which recognizes the 5′-triphosphate of uncapped RNA (Hornung *et al.*, 2006). The formation of the 5′-cap is catalyzed by viral capping machineries, which include RNA triphosphatase (RTPase), guanylyltransferase (GTase), 7-N-methyltransferase (N7-MTase), and 2′-O-methyltransferase (2′O-MTase) activities (Fig. 6(C)). One major structural difference between turreted and non-turreted dsRNA viruses of the *Reoviridae* family is the location of their capping enzymes. In non-turreted dsRNA viruses, such as rotavirus and BTV, the capping enzyme likely associates with the RdRp inside the virus core (Fig. 6(J)). In contrast, in turreted dsRNA viruses, such as orthoreovirus, ARV, and CPV, the capping enzyme is external to the core layer and forms the turret-like feature (Fig. 6(J)).

The in situ cryo-EM structure of rotavirus showed that the mRNA exit channel faces the pore at the fivefold axes. How does the RNA transcripts get capped by the capping enzyme? One hypothesis is that the base-paired (–)RNA template/(+)RNA product emerges through the template exit channel and encounters VP3 for RNA capping. The capped transcript then re-threads and enters the transcript exit channel (Jenni *et al.*, 2019). It might be because rotavirus VP3 does not anchor to a fixed location on VP2 capsid or VP1 RdRp. However, the in situ cryo-EM structure of rotavirus did not resolve any density for VP3 to allow determination of the structure of rotavirus VP3 and how it coordinates with VP1 to cap the nascent transcript exiting from VP1. Recently, cryo-EM and X-ray crystallography analyses of recombinant full-length VP3 revealed the atomic details of how the catalytic domains for mRNA capping are assembled in line (Fig. 6(D)) (Kumar *et al.*, 2020). Intriguingly, the rotavirus VP3 forms a stable tetramer both in solution and in crystals by the association of antiparallel dimers (Fig. 6(E)), which may have functional roles in mRNA capping and anti-interferon response mediated by the C-terminal PDE domain of VP3 (Ogden *et al.*, 2015; Kumar *et al.*, 2020). In BTV, the crystal structure of RNA-capping enzyme VP4 has been determined, and it assembles all four enzymatic activities with a directional layout (Fig. 6(F)) (Sutton *et al.*, 2007). Similar to the rotavirus VP3, BTV VP4 forms dimers in solution and also in crystals along a

(G) Dimer of BTV VP4 formed along a crystallographic two-fold axis and viewed in ribbon and surface representations as in (E). (H) Structure of ARV turret protein VP1 (PDB 5ZVT). (I) Pentamer of ARV turret protein VP1 viewed perpendicular to or along the 5-fold axis in ribbon and surface representations as in (E). (J)–(K) Mechanisms of RNA transcription and replication of non-turreted (left panel) and turreted (right panel) dsRNA viruses.

crystallographic two-fold axis (**Fig. 6(G)**), suggesting that the oligomeric formation of the capping enzyme might be a common structural mechanism in the non-turreted dsRNA viruses.

Viruses of the turreted *Spinareovirinae* subfamily have the capping enzyme located at the 5-fold vertices. Reovirus $\lambda 2$ forms a pentameric turret with the active sites facing the interior tunnel of the turret. The nascent mRNA exits through these tunnels while being capped by $\lambda 2$ (Reinisch *et al.*, 2000) (Figs. 3(B) and 5(B)). Similarly, in ARV and CPV, the pentameric turret contains the capping domains, which are connected by unique channels to allow the sequential GTase, 7 N7-MTase, and 2'O-MTase enzymatic reactions (**Fig. 6(H)** and **(I)**) (Cheng *et al.*, 2011; Wang *et al.*, 2018; Ding *et al.*, 2018; Cui *et al.*, 2019). However, the turrets themselves do not contain the RTPase activity, which cleaves the 5'- γ -phosphate of nascent (+)RNA to allow the addition of GMP and formation of the 3'-GpppG 5'-cap structure. Instead, the associated NTPase likely catalyzes the hydrolysis of the 5'- γ -phosphate.

Genome Replication and Packaging

Viroplasm or Replication Factories

In viruses of the *Reoviridae* family, mRNAs are released from viral particles and translated to synthesize viral proteins that form condensed inclusions termed viroplasms, viral factories (VFs), or viral inclusions (VIs) in the cytosol (Tenorio *et al.*, 2019; Borodavka *et al.*, 2018; Roy, 2017) (**Fig. 3**). These inclusions contain viral genomic RNA and structural proteins that package into progeny viruses, as well as NSPs that regulate viral genome replication and packaging (Hu *et al.*, 2012b). In rotavirus, NSP2 and

Fig. 7 Structure of nonstructural RNA binding proteins that form the viroplasms. (A) Structure of rotavirus NSP2 (PDB 1L9V). NSP5 are essential for viroplasm formation, and genome replication and packaging. NSP2 is a multifunctional protein that exhibits nucleoside triphosphatase (NTPase), nucleoside diphosphate kinase (NDP kinase), RNA triphosphatase (RTPase), single-stranded RNA binding, and helix destabilizing activities (Hu *et al.*, 2012b). The crystal structure of rotavirus NSP2 revealed that the catalytic center of NSP2 resembles the histidine triad (HIT) of cellular nucleotidyl hydrolases (Jayaram *et al.*, 2002; Taraporewala *et al.*, 2002; Taraporewala and Patton, 2001; Taraporewala *et al.*, 1999) (Fig. 7(A)). The full-length recombinant NSP2 protein exists as octamers in solution (Fig. 7(B)). Cryo-EM studies of NSP2 alone or in complex with either NSP5 or RNA showed that NSP2 exists as octamers in solution and binds to NSP5 and RNA at the same site (Jiang *et al.*, 2006). In addition, NSP2 also interacts with RdRp VP1 and the N-terminal hub of the core capsid protein VP2 (Viskovska *et al.*, 2014). These data support a model that NSP2 may function as a molecular motor using energy from NTP hydrolysis to destabilize the mRNA template and feed it to the RNA template to VP1 during genome replication. The existing biochemical data suggest that rotavirus NSP2 is functionally homologous to NS2 of BTV (Fillmore *et al.*, 2002; Taraporewala *et al.*, 2001; Zhao *et al.*, 1994), and σ NS of orthoreovirus (Gillian and Nibert, 1998). The NS2 of BTV is critical for viral inclusion body formation and recruits viral RNA and viral proteins for virus core assembly. The crystal structure of the RNA-binding domain of BTV NS2 (residues 1–177) has a β -sandwich structure and assembles into dimers in crystal packing (Butan *et al.*, 2004) (Fig. 7(C) and D). Small-angle X-ray scattering analysis of the C-terminal domain of NS2 showed that it forms an elongated dimer. Electron microscopy of the full-length protein showed some ring-like structures, providing a basis for the proposed model for a decamer of the full-length protein (Mumtsidu *et al.*, 2007). Interestingly, in the turreted Rice black streaked dwarf virus (RBSDV), a member of the genus *Fijivirus* in the family *Reoviridae*, the P9–1 protein also accumulates in viroplasm inclusions. Crystallographic analysis of RBSDV P9–1 protein revealed that it assembled into octamers, remarkably resembling the octamer formation of rotavirus NSP2 (Fig. 7(E) and (F)) (Akita *et al.*, 2012). In cells infected by turreted reovirus, viral non-structural proteins μ NS and σ NS and structural protein μ 2 regulate the formation of VIs (Broering *et al.*, 2002; Becker *et al.*, 2003). However, the structural basis of how the replication factories are formed remains unknown due to the lack of structures of reovirus μ NS or σ NS.

Replication and Packaging

The viral mRNA transcripts are used not only for the translation of viral proteins but also for the synthesis of (–)RNA to produce dsRNA genome within viroplasm (Figs. 3 and 6(K)). It remains unclear how the dsRNA viruses precisely assort, assemble, and package a complete set of gene segments into progeny viruses. Although the detailed structural information is still unknown, it has been proposed that specific recognitions via RNA–RNA interactions result in the clustering of a set of the dsRNA segments during genome packaging (Pesavento *et al.*, 2006). In rotavirus, the RdRp VP1 specifically recognizes the 3′-consensus sequence (3′-CS) in the template-entry channel (Lu *et al.*, 2008). In addition, VP1 extensively interacts with VP2 of the innermost layer and stabilizes the VP2 decamers (Jenni *et al.*, 2019). This interaction with VP2 initiates the synthesis of (–)RNA by RdRp VP1, thereby coordinating RNA replication with the assembly of the virus core. *In vitro* biochemical assays using recombinant proteins showed VP1 is only active when VP2 is present (Patton *et al.*, 1997). Using cell-free reconstitution and reverse genetics systems, it has been suggested that BTV (+)RNAs assort and assemble into large complexes before being incorporated into the core particles (Periz *et al.*, 2013). The 5′- and 3′-UTRs mediate the trans-acting RNA–RNA interactions (tRRIs) between gene segments and facilitate the packing of the entire genome.

Other dsRNA Virus Families

Most dsRNA viruses that have been structurally characterized are icosahedral non-enveloped particles, except the *Cystoviridae* family, which has enveloped viruses with a genome of three dsRNA segments and a double-layered protein capsid. For instance, the bacteriophage ϕ 6 has three structurally defined layers. Its outermost layer contains a lipid bilayer envelope formed by viral integral membrane proteins (P6, P9, P10, and P13) and cellular phospholipids. The cellular attachment spike protein P3 is anchored onto the envelope via a fusogenic protein P6. The nucleocapsid is formed by two concentric icosahedrally organized protein layers. The outer layer of the nucleocapsid is formed by P8 trimers with $T = 13$ icosahedral symmetry (Poranen *et al.*, 2017) generally similar to the organization of the middle layers in the members of *Reoviridae* such as rotavirus and BTV. The core capsid layer is formed by the capsid protein P1, the RdRp P2, the NTPase P4 with a hexameric clustering, and the assembly cofactor P7. The asymmetric P1A–P1B dimers arranged with $T = 1$ symmetry, enclosing the genome of three dsRNA segments which adopt a dsDNA-like single-spoiled genome organization (Ilca *et al.*, 2019). Another dsRNA virus that is structurally well characterized is the λ -A virus, which belongs to the *Totiviridae* family. Interestingly, it has a single capsid layer that encloses a single dsRNA segment genome. Remarkably, this capsid layer with 120 capsid protein subunits follows the same organization of the innermost capsid layers observed in the *Reoviridae*, suggesting an evolutionary hierarchy in dsRNA viruses (Naitow *et al.*, 2002; Bamford *et al.*, 2005).

Conclusions

Members of the *Reoviridae*, the largest and most diverse dsRNA virus family, exhibit enormous structural diversity in their outer capsid proteins, which might be the molecular determinants of the host specificity, tissue tropism, and pathogenesis of the viruses.

Nonetheless, they also display remarkable structural conservation particularly in the organization of the inner capsid layers to support the common requirement of endogenous transcription. Combined with the structural information gained through X-ray crystallography and cryo-EM, the structural basis of cellular attachment mediated by the outer capsid proteins, the capping mechanisms of mRNA, endogenous transcription, and viroplasm formation have begun to emerge in recent years. However, many fascinating questions still remain that perhaps can be approached by further advances in the structural techniques particularly in cryo-EM techniques, which probably are more suitable to address such questions. Through these studies, we can anticipate significantly more detailed insight into receptor(s) recognition, mechanisms of virus entry into cells, how the outer layer is removed to deposit the transcriptionally active form of the particle in the cytoplasm, formation of the replication factories, mechanism of immune evasion, genome reassortment and packaging, and exiting from infected cells. Further structural studies will be needed to understand how the capping enzymes, such as rotavirus VP3 and BTV VP4, are located in the non-turreted dsRNA viruses and how they coordinate with the viral RdRps during transcription and virion assembly. Also, the atomic models of many viral non-structural proteins, for example, the rotavirus NSP1, NSP4, NSP5, and NSP6, the reovirus μ NS and σ NS, are still unknown. These NSPs are critical players during virus replication and may serve as potential candidates for antiviral development. Another aspect of the replication of the dsRNA viruses not discussed here is how these viruses are released from infected host cells. Although biochemical studies suggest that there are multiple mechanisms by which the dsRNA virus egress from host cells, little structural information about this process is known. For instance, the progeny of rotavirus is released from non-polarized kidney epithelium cells via direct cell lysis but traffics to the apical surface and is secreted from polarized intestinal epithelial host cells. Future in situ structural studies of the infected cells using electron cryotomography (cryoET) may yield more molecular and mechanistic details about these processes.

Nomenclature

CATC Capsid-associated tegument complex
cryo-EM Cryo-electron microscopy
dsDNA Double-stranded DNA
EBV Epstein-Barr virus
HCMV Human cytomegalovirus
HK97 Hong Kong 97

HSV Herpes simplex virus
KSHV Kaposi's sarcoma-associated herpesvirus
MCP Major capsid protein
MTP Major tail protein
SCP Smallest capsid protein
TMP Tape measure protein
VZV Varicella-zoster virus

Glossary

Capsid or head Icosahedral shell that encloses the genomes of tailed phages and herpesviruses.

Concatamer Continuous nucleic acid molecule made up of multiple head-to-tail linked unit-length viral genomes.

Cryo-electron microscopy (cryo-EM) Image reconstruction-based structural biology technique that has been used in recent years to describe the structure of viruses and viral macromolecules at atomic or quasi-atomic resolution.

Genome packaging Viral cycle process by which the genome is encapsidated into preformed procapsids or proheads.

Portal Dodecameric ring-like assembly located at a unique capsid vertex that plays a key role during genome ejection, procapsid morphogenesis and genome packaging processes.

Procapsid or prohead Immature form of the capsid or head that is a necessary precursor for the genome packaging process.

Tail Appendage machinery of the *Caudovirales* structure involved in host recognition and genome delivery.

Tegument In mature herpesvirus virions, proteinaceous cluster located in the space between the capsid and the envelope.

Triangulation (T) number Number of smaller triangles (facets) contained in each of the 20 faces of the icosahedral capsid. The number of coat protein subunits in an isometric virus is calculated as 60 T, because there are three subunits per facet.

Virion Mature viral particle. In bacteriophages, it comprises the capsid filled with the genome and the tail. In the case of herpesviruses, it is formed by the lipidic envelope, the tegument and the capsid with the genome.

Introduction

This article reviews the structure of tailed phages and herpesviruses. Although their respective hosts are very distant from a phylogenetical perspective, these two viral groups share some morphology features that suggest an evolutionary linkage between them with a putative ancient common ancestor.

The chapter starts with a separate explanation of the architecture of tailed phages and herpesvirus virions, and then both are compared from a structural point of view. In this regard, it is important to mention that in recent years the “resolution revolution” provided by cryo-electron microscopy (cryo-EM) has made a significant contribution to the structural virology field, with many new atomic or quasi-atomic models available for both whole viral particles and specific protein complexes. The combination of such information with that yielded by X-ray crystallography offers an unprecedented amount of knowledge about tailed phage and herpesvirus virion architecture. Finally, the last section of the article gives an insight into the structural basis of key processes during the viral infection cycle.

Tailed Phages

Prokaryote-infecting viruses, which are called bacteriophages or phages, present enormous diversity in terms of morphology and type of nucleic acids that form their genome. Among these viruses, the *Caudovirales* order comprises the so-called double-stranded DNA (dsDNA) tailed phages, probably the most abundant type of organisms on Earth and found in a wide range of ecosystems. First discovered independently by Frederick W. Twort and Felix d’Herelle (1915 and 1917, respectively), some *Caudovirales* species have been extensively used as model organisms in biochemistry, genetics and molecular biology studies. Moreover, phage therapy emerged as a potential treatment for bacterial diseases, but the discovery of antibiotics reduced research in that field. However, the appearance of multidrug-resistant bacteria is now reigniting interest in therapeutic applications for phages.

Caudovirales are thought to be among the oldest microorganisms on Earth because they are able to infect both Bacteria and Archaea. Genome comparison studies show a huge genetic diversity among tailed phages, revealing a mosaic nature caused by frequent homologous recombination and horizontal gene transfer events. Nevertheless, all *Caudovirales* species present a shared morphology, with an overall architecture of the virion or mature viral particle outside host cells consisting of two main structural elements, namely a head, which encloses the genome, and a tail appendage, which is in charge of host recognition and dsDNA delivery into the cell.

Icosahedral Head or Capsid

Phage heads are typically icosahedral, which is the cubic point symmetry arrangement that offers a lowest surface/volume ratio and therefore the most economic from a genetic point of view. Icosahedrons are formed by 20 triangular faces and contain three types of symmetry axes (two-fold, three-fold and five-fold) that yield 60 equivalent positions. However, heads may contain more than 60 structural subunits in not strictly equivalent positions when each face of the icosahedron is built by more than one smaller triangle or facet. The triangulation number (T) is used to define the specific geometric arrangement of each head, as it reflects the number of facets present per face. There is a relationship between the number of structural subunits present in a virus and its T number, the former being around 60 times the latter because there are 20 faces per virion and three equivalent structural subunits per facet. It is important to mention that around 15% of tailed phage species have heads that do not present isometric icosahedral symmetry, but rather show a prolate or elongated morphology with a tubular middle section between two icosahedral ends. In these cases, previous estimation of the number of major capsid proteins (MCPs) present is not correct, and structural subunits in the middle section should also be included in the calculation.

The structural subunits that comprise the head are called capsomers, which are either hexamers or pentamers of the MCP, named hexons and pentons, respectively. Hexons form the capsid faces and edges, while pentons are located at eleven of the five-fold vertices, all but one holding the portal protein. In phages with prolate heads, the portal vertex is located at one end of the long axis of the head. Given that the portal vertex also has five-fold symmetry and the portal is a ring-shaped dodecamer, there is a symmetry mismatch, which means that there cannot be identical interactions between portal and MCP subunits. In some phages, other proteins associate with the MCP's, sometimes stabilizing the head and building connections between capsomers. Finally, it is important to mention that some phages contain head fibers protruding from the capsid.

T4 phage, for instance, presents a prolate head comprised mainly of the MCP gp23, which forms the hexons. Although pentamers are usually formed by the same MCP, T4 pentons are built with the capsid vertex protein gp24, which is found in eleven vertices. The N-terminal ends of both gp23 and gp24 are cleaved in mature capsids. A gp20 dodecamer is located at the unique vertex, building the portal. Moreover, the small outer capsid (Soc) and highly immunogenic outer capsid (Hoc) proteins are also found at the outer surface of the mature head. The former provides the head with stability against extreme temperatures and pHs, while the latter is probably involved in the infection of the *Escherichia coli* host (Fig. 1(A)).

The main function of phage heads or capsids is to contain the viral genome and protect it from the environment when virions are outside the host cells. Given that tailed phages do not need to disassemble upon cell infection in order to release the genome, because it is ejected from a unique capsid point, heads can be built as highly stable shells. Moreover, capsids are extremely resistant since the genome is packaged inside them at near-crystalline densities (> 500 mg/mL), which causes huge internal pressures. Apart from the genome, the head of some phages also contains an inner core of proteins, usually assembled at the unique vertex interacting with the portal. The core proteins typically form a cylindrical structure with a central channel continuous with that of the portal. Core proteins are thought to have important functions during genome ejection.

Several models suggested distinct arrangements of the genome in the form of solenoids, liquid crystals or folded toroids inside phage heads. High-resolution structures have now revealed concentric shells at regular intervals within the capsid corresponding to the genome. In phages with an inner core, the dsDNA is spooled around it and in some cases density corresponding to DNA is observed in the center of the core protein channel. Moreover, some structures also indicate the presence of dsDNA within the portal and proximal part of tail channel, with the genome ready to be injected upon infection of the host cell.

The unique vertex where the portal is found is associated with a number of specific functions. It is where the DNA packaging and ejection processes occur and the docking point where neck and/or tail proteins attach. Therefore, the phage portal is sometimes also referred to as connector, because in mature virions it links the head to the rest of the particle.

Tail

The main function of the tail is to contact the host cell during infection and to deliver the genome into its cytoplasm. Most tails present protruding elongated proteins called fibers whose tip domains are key for host cell recognition and binding. The tail is assembled at the portal vertex and it attaches to the head by specific protein complexes called collar, gatekeeper or adapter. Directly interacting with the portal, these are proteins with a dodecameric architecture containing four α -helices per monomer, an arrangement that is conserved in the different phage families. In some cases, a second ring formed by β -sheets called stopper has been described to build a plug that closes the channel.

Classical taxonomic studies of phages were strongly based on the virion morphology when observed by negative stain electron microscopy. Therefore, the *Caudovirales* order comprises three families depending on the morphology and complexity of their tails:

Fig. 1 Structure of tailed phages virions. (A) T4 isomeric head (PDB 5VF3) formed by the MCP building the hexons (blue), the capsid vertex protein (green), the small outer capsid protein (orange) and the highly immunogenic outer capsid protein (pink). The structural assembly depicted in the zoom is repeated 60 times in order to build the whole isometric capsid. (B) Fiberless T7 tail complex (PDB 6R21) comprising the portal (magenta), adapter (yellow) and nozzle (dark blue) proteins fitted into the tail volume (EMD-5689). Regions corresponding to the fibers are also indicated.

Podoviridae have short non-contractile tails, *Siphoviridae* long non-contractile tails and *Myoviridae* long contractile tails. However, as tail structure must be able to adapt to each specific host cell, they are quite variable even among the same family. At this point, it is important to comment that new insights into phage evolution might question the utility of the classical taxonomic families. Nevertheless, the aforementioned classification based on the tail morphology is still the one most widely accepted.

Podoviridae

Viruses of this family present short simple tails that are assembled directly into the viral head and attached to the portal by the adapter protein. Most of the known *Podoviridae* tail structures are formed by a central nozzle that interacts with the fiber appendages.

Analysis of the available structures shows specific differences depending on the phage. For instance, P22, which infects *Salmonella typhimurium*, has a plug for the DNA channel with a trimeric needle-like structure that is released to penetrate the cell envelope during infection. Another example is the *Bacillus subtilis* phage Φ 29, where 12 trimeric fibers are bound to its collar region. *Podoviridae* also includes T7 phage, which infects *E. coli* and whose fiberless tail structure in complex with the portal protein was solved (**Fig. 1(B)**). The cryo-EM 3.3 Å resolution structure shows a dodecameric adapter that interacts directly with the hexameric nozzle, whose fold is organized around six central seven-bladed β -propellers, one per monomer. The β -propellers are placed with their planes radial and are essential to tightly close the channel gate in the mature phage. The remaining domains of the protein are organized around them.

Siphoviridae

This family is characterized by a relatively well conserved long non-contractile flexible tail formed mainly by a long-tube built by copies of a major tail protein (MTP) organized in the form of a ring of homohexamers. Tail tube length is determined by the tape measure protein (TMP), located at the tube channel, and the terminator protein, which is found at the end proximal to the head. These two proteins act together to stop the polymerization of the MTP once the required size of the tail has been reached. Finally, the absorption apparatus is a variable host recognition device found at the distal end of the tail. Some *Siphoviridae* contain a baseplate structure, although this complex architecture is more typical of the *Myoviridae* family.

One of the most studied *Siphoviridae* is the *E. coli*-infecting λ phage, which presents a 150 nm long tail while its head has a diameter of only around 63 nm. Although this phage presents side tail fibers, most laboratory strains carry a mutation that eliminate them. Its MTP, gpV, has two domains, and its N-terminal one has a fold which is conserved among proteins of different phage families. Another well-known *Siphoviridae* phage is SPP1, which infects *Bacillus subtilis*. The structure of its tail has been studied by electron microscopy, showing a rotation of around 21° between adjacent hexameric rings of the MTP. Other members of this family are T5 and Hong Kong 97 (HK97), which infect *E. coli*, and the thermophilic phage P23-45, which infects *Thermus thermophilus*.

Myoviridae

Viruses belonging to the *Myoviridae* family have long contractile tails, which are formed by the following parts: the baseplate, which is the part in charge of the contact with the surface of the host cell; the sheath, which builds the outer protein cylinder of the tail and provides a contractile capacity; the tail tube, which assembles the inner part of the channel; and fibers, which recognize the host. Moreover, TMP and terminator proteins have also been described to regulate the length of the tail, and some *Myoviridae* terminators are homologous to that of the λ phage.

A prototypical member of *Myoviridae* is the *E. coli*-infecting T4, which has a complex 100 nm long tail and a head width of 85 nm. Its head and tail are connected by a neck, which presents a thick collar formed by hexameric rings with protruding whiskers that control the extension of the fibers. The tail tube is the scaffold for sheath assembly, which is formed by 23 stacked hexameric rings. The T4 baseplate contains at least 16 different proteins and also has 6-fold symmetry. Long and short tail fibers protrude out of the baseplate, but the short ones are folded under it until the long ones contact the primary cellular receptor. Only then do short fibers also unfold and recognize a secondary receptor. Other well-known phages of the *Myoviridae* family include Mu and P1, which also infect *E. coli*.

Herpesviruses

Herpesviridae is a family of enveloped dsDNA viruses able to infect eukaryotic cells. Herpesviruses infect many animal species, including mammals, fishes, birds, amphibians, reptiles and some types of invertebrates. Although herpesvirus-caused diseases have been known for centuries, these viruses were not detected until the beginning of the 20th century. The following nine herpesviruses belonging to three distinct subfamilies are known human pathogens: herpes simplex virus types 1 and 2 (HSV-1, HSV-2) and varicella zoster virus (VZV) are *Alphaherpesvirinae*; human cytomegalovirus (HCMV) and roseolovirus (human herpesvirus 6A, human herpesvirus 6B and human herpesvirus 7) are *Betaherpesvirinae*; and Epstein-Barr virus (EBV) and Kaposi's sarcoma-associated virus (KSV) are *Gammapherpesvirinae*. Herpesviruses have a wide range of pathogenic effects in humans, from inapparent or mild to life-threatening, and some have been linked to specific types of cancer. For instance, EBV is associated with lymphomas and gastric and nasopharyngeal carcinomas. After primary infection, herpesviruses remain latent in host tissues throughout lifetime and retain the capacity to reactivate under certain conditions, causing recurrent diseases.

Mature herpes virions are enveloped spherical particles with a diameter of around 200 nm. Inside the lipidic envelope there is a capsid containing the genome (also called nucleocapsid) and covered by a proteinaceous tegument.

Herpesvirus genomes in mature virions are single linear dsDNA molecules containing 120–300 kbp. They are made up of two covalently linked components, named U_L and U_S , and contain terminal repeats. During the latency phase, viral genomes are usually maintained as circular episomes replicated by the cellular machinery, and at low frequencies they may be found integrated in the host chromosomes. Within the capsid, they are found in a near-crystalline state, in a left-handed spool forming concentric shells around a disordered, ellipsoidal dsDNA core.

The capsids of herpes virions are icosahedral and they have a diameter of around 120–130 nm. They have a structure similar to that of non-prolate phage heads and are formed by 161 hollow capsomers (150 hexons and 11 pentons) plus the portal located at a unique five-fold vertex. The MCP subunits are joined in 3-fold symmetry points by triplex structures, which contain two copies of one protein plus a single copy of another one. These triplex structures serve to join capsomers and stabilize the viral shell. Capsids may contain small amounts of other viral proteins.

The tegument, which is made of partially amorphous proteinaceous globular material, surrounds the capsid. It has an asymmetrical distribution, with the capsid not necessarily located at its center, and presents poor structural definition except for a certain degree of icosahedral arrangement in the region closest to the capsid. The pleomorphic tegument is formed by around 20 different proteins encoded in the viral genome, and several of them are related to herpesvirus gene expression. Tegument proteins are less conserved among species than capsid proteins.

Both the nucleocapsid and the tegument are surrounded by the envelope, a lipidic bilayer decorated with glycoproteins. Such macromolecules are important for the subsequent infectivity of the virions, as they interact with cell receptors prior to the fusion of the host membrane cell with the viral envelope. Glycoproteins can be virus-encoded or have a cellular origin, and when virions are visualized by negative stain microscopy they look like projecting spikes on the surface of the particle.

Regarding *Alphaherpesvirinae*, a cryo-EM structure of the HSV-1 capsid with proteins of the capsid-associated tegument complex (CATC) is available at 4.2 Å resolution (Fig. 2(A)). The $T = 16$ capsid contains pentons, three types of hexons (peripentonal, edge and center) and six types of triplexes (Ta to Tf). Atomic models are available for the MCP (VP5), the triplex dimer protein (VP23), the triplex monomer protein (VP19c) and the smallest capsid protein (SCP, VP26). At capsid vertexes, there are five copies of the star-shaped heteropentameric CATC, containing two copies of pUL25 and pUL36, respectively, and a single copy of pUL27. Each CATC is formed by a region contacting with the triplexes, an extended five-helix bundle, and a head region placed between two MCP subunits of the penton. The C-terminal α -helix of pUL36 is thought to mediate the linking of the capsid to the outer tegument and envelope, as it interacts with other tegument proteins that have contact with envelope glycoproteins. An equivalent structure of HSV-2 has also been solved by cryo-EM at 3.75 Å, and in both cases CATC seems to contribute to the exceptional stability of HSV virions, thereby reinforcing the most stressed parts of capsids, the vertexes.

HCMV, which belongs to the *Betaherpesvirinae* subfamily, has a large 235 kbp genome, although the size of its capsid is similar to that of the herpesviruses previously described. Therefore, the effect of the highly pressured genome is even more remarkable in this case. A 3.9 Å resolution cryo-EM structure reveals the presence of capsid stabilization mechanisms conserved across herpesviruses, based on

Fig. 2 Structure of herpesviruses virions. A. HSV-1 capsid (EMD-7472 and PDB 6CGR). The cryo-EM map is in gray, and the zoomed region shows the atomic structures of the MCP (pink), the small capsomere-interacting protein (blue), the triplex capsid proteins 1 and 2 (green forest and green, respectively), the capsid vertex components 1 and 2 (orange and orange-red) and the large tegument protein deneddylase (yellow). The structural assembly depicted in the zoom is repeated 60 times in order to build the whole capsid. B. Structure of the unique vertex portal (EMD-9861, PDB 6OD7 and PDB 6ODM). The map appears in gray, and atomic models of the same proteins as in panel A with the same color code are shown for one of the 5-fold symmetry components building the vertex. The atomic model of the dodecameric portal is depicted in light blue.

the role of MCP subunits and triplexes. Moreover, some specific features have been described, such as the presence of hexon channels accommodating parts of the genome and facilitating the packaging of DNA, and the role of a *Betaherpesvirinae* specific tegument protein, pp150, which interacts with the SCP and builds a layer that further stabilizes the capsid. The structure of human herpesvirus 6B shows that the pp150 homologous protein, pUL11, is also present on the surface of the capsid but in lower amount. This observation suggests that the significantly smaller genome size of the virus (162 kbp) diminishes the need for stabilization.

CATC homologs have also been described in *Gammaherpesvirinae*, as shown by the structure of KSV. However, they present a lower occupancy compared to those present in the other herpesviruses, with a long-range asymmetric attachment determined by the unique portal vertex. CATCs are preferentially associated with this vertex and the portal-proximal sides of the penton vertices. Therefore, the binding of CATC seems to be penton-independent and would depend on contacts with peripentonal hexons and triplexes.

Structures of the portal vertex obtained using symmetry-relaxation cryo-EM strategies have also provided more insights into the architecture of the unique capsid vertex, which has sometimes been described to present a tail-like structure. Tentacle-like helices extend from the HSV-1 portal base to an outer vertex-capping density that anchors the genome terminus, which extends outside of the portal protein channel (**Fig. 2(B)**). Both helical structures present a five-fold symmetry like the capsid vertex, which produce a symmetry mismatch with the dodecameric portal.

Structural Comparison of Tailed Phages and Herpesviruses

As mentioned at the beginning of the article, structural and functional similitudes between tailed phages and herpesviruses suggest a phylogenetic linkage between them. Both share certain replication and transcription patterns, and in some cases plasmid-type and integrative lysogeny processes.

Regarding the mature architecture of tailed phages and herpesviruses, the main difference is that while the former are non-enveloped particles, the latter do have an envelope. Therefore, the crucial role of protecting the genome from the environment is performed entirely by the capsid shell in the case of tailed phages while in herpesviruses the envelope and tegument also play an important role. Nevertheless, phage heads and herpes capsids share the icosahedral arrangement built by equivalent organizations of their capsomers and have a portal, which is crucial during capsid assembly and genome encapsidation and release processes. The heads of tailed phages show significant differences in their T numbers, while herpesviruses have always a T number of 16, which is within the range of known arrangements described for tailed phages.

MCP Fold

Sequence similarity matches to assess evolutionary relationships may fail when homologous proteins have diverged significantly. However, in such cases, structural analysis can be useful to detect evolutionary relationships. The most widely studied structural feature shared between mature virions of tailed phages and herpesviruses is the conserved fold of the MCP. Structural data have shown that

Fig. 3 MCP HK97-fold conservation. Monomeric MCP structures. First line corresponds to phage proteins: T7 (PDB 3J7V), P22 (PDB 5UU5), HK97 (PDB 1OHG), P23-45 (PDB 6I9E) and T4 (PDB 5VF3). Second line corresponds to herpesvirus proteins: HSV-1 (PDB 6CGR), HSV-2 (PDB 5ZZ8), HCMV (PDB 5VKU), human herpesvirus 6B (PDB 6Q1F) and KSV (PDB 6PPB). Structures are depicted with the same orientation with α -helices in red, β -strands in yellow and loops in light blue. The tailed phages HK-97 fold is conserved in the floor domain of the herpesvirus proteins, at the bottom region of their structure.

MCP topology is conserved, and both types of viruses form the so-called HK97 lineage, as they share the basic fold of the phage HK97 MCP, the first homolog described (Fig. 3). The structure of the HK97 MCP was determined by X-ray crystallography, and although it does not share sequence similarity with the MCP of other phages, available structures have shown that proteins from phages belonging to different families, including T4, P22 or Φ 29, share the same fold and arrangement. In the case of T4, both the MCP and capsid vertex proteins have the HK97 fold. Basically, this fold consists of three domains: the A domain, the P domain and the E loop. The A domain, with a V-shape, builds the apex of the capsomers. The P domain typically consists of a long α -helix plus a β -sheet formed by three β -strands, and it is found at the capsomer periphery. Finally, the E loop expands from the P domain and performs contacts between neighboring subunits of the MCP in the capsid shell. However, the conserved fold of each viral species has modifications, thereby conferring the viruses specific characteristics and abilities.

In the case of HK97, crosslinking between MCP subunits has been described, with the E loop covalently bound to the P domain of another MCP placed on an adjacent capsomer. In the case of T4, the capsid vertex protein contains an extra insertion domain (I-domain) that binds to neighboring subunits from the same penton and MCP subunit from another capsomers by non-covalent interaction in equivalent location to those where crosslinking occurs in the case of phage HK97.

The phage P23-45 presents an increased spacing between capsomers in the icosahedral lattice, that allows the virus to build larger capsids able to fit bigger genomes. MCP presents an extended A-domain and a longer E loop. In mature P23-45 virions, the E-loops become well-defined β -strands that create a binding site for the N-terminal part of auxiliary surface proteins, which stabilize three-fold axes.

Regarding herpesviruses, the MCP is much larger, and although they contain the HK97 fold, they also have other domains. It is the floor domain that has the overall shape of the structural signature with conserved disposition of the secondary structure elements, while the middle and upper domains that form the capsomer towers are more divergent, even among herpesvirus families.

The canonical HK97 fold is not limited to viruses infecting bacteria and eukaryotes but has also been described in archaeal head-tailed viruses, like in the 8.9 Å resolution cryo-EM structure of the *Haloarcula sinatiensis* tailed virus 1 (HSTV-1). Therefore, viruses from archaea, bacteria and eukaryotic domains are evolutionarily connected, suggesting that viruses appeared before the three domains split a few billion years ago. Structural data suggest that this fold is a basic element on which to build stable capsids while at the same time it allows some conformational flexibility required during capsid morphogenesis and maturation.

Commonality between tailed phages and herpesvirus capsids is not restricted to the MCP fold. The architectures of triplex proteins also have a conserved fold with respect to the gpD auxiliary cementing protein from λ phage, which has β -strand identical topology. It has been suggested that evolution may have diversified the strategies of different viruses depending on the size of their genomes. While the cementing protein may have been replaced by the crosslinking process in the case of HK97, the size of the herpesviruses genomes requires the presence of triplexes.

Portal Protein

The portal proteins of different species differ in size and sequence, but there is a common structural architecture composed of 12 subunits of a single protein arranged in a ring-shaped dodecamer with a central channel (Fig. 4).

Fig. 4 Portal protein fold conservation. Portal structures are shown both as dodecamers and monomers. First column corresponds to phage proteins: T7 (PDB 6QX5), P23-45 (PDB 6IBG) and T4 (PDB 3JA7). Second column corresponds to herpesvirus proteins: HSV-1 (PDB 6OD7), EBV (PDB 6RVS) and KSV (PDB 6PPI). Structures are depicted with the same orientation with α -helices in red, β -strands in yellow and loops in light blue.

The following portal domains have been classically described for the portal of tail phages: the crown, inserted into the head interacting with the inner core if present; the wing, at the outermost part interacting with the capsid proteins; the stem, which builds the middle section of the channel wall, and the clip, located at the distal part with respect to the capsid and interacting with the adapter/gatekeeper in mature virions and with the terminase during packaging. Available structural data obtained both by X-ray crystallography and cryo-EM show that the most conserved region comprises the 24 helices of the stem domain, which forms the central part of the channel, while the wing and crown present a significant variability in size and shape. Given that the portal serves as a conduit for dsDNA passage, one of the most interesting parts of its structure is the channel region. An α -helix from the wing protrudes into the channel, and a flexible tunnel loop connects the protruding α -helix to one of the stem α -helices.

In the case of herpesvirus portals, the atomic structures of HSV-1, EBV and KSV were recently solved by cryo-EM, revealing a similar structural arrangement, also containing the characteristic stem 24 α -helices, but with some differences. Regarding the channel region, the two narrowest points have been defined for these three viruses. First, in an equivalent position to that of the protruding α -helix from tailed phages, there is a β -hairpin with a small tunnel loop between the two β -strands, forming an aperture perpendicular to the portal channel axis. Second, the region equivalent to the clip holds a β -barrel, formed by three β -strands per monomer arranged almost parallel to the channel axis. Each group of β -strands contains two parallel β -strands from the same monomer while the third one is antiparallel and comes from the clockwise neighbor. The portal structures of these three herpesviruses have a missing fragment, which should be located extending from the β -barrel clip. It has been hypothesized that the missing residues build the five sets of tentacle-like helices extending towards the cap, but this would imply a symmetry mismatch inside the same protein.

Structural Insights Into the Infective Viral Cycle

Similarities between tailed phages and herpesviruses go beyond their mature structures. Interestingly, they share some similar mechanisms along the whole viral infection cycle. The following sections review the main stages of this cycle, highlighting the differences from a structural and functional perspective when present.

Genome Ejection

The process by which the linear dsDNA molecule exits the viral particle when it infects a new host cell is called genome ejection. The genome of tailed phages and herpesviruses is released from the icosahedral capsid via the portal vertex, which acts as a channel

for dsDNA passage. However, many differences arise apart from that, given that the whole architecture of the virus and host cells to infect are very different.

In the case of phages with a tail, they do not enter the cell and therefore require sophisticated machineries to overcome the cell wall and plasmatic membranes. It is important to take into account that such appendages do not act like syringes, in fact dsDNA entry into the host cells is mainly passive as a result of dense packaging under very high pressure. In some phages, like T7 and $\Phi 29$, there is an initial passive ejection followed by a pause, after which injection resumes when proteins expressed from the first part of the genome ejected into the cytoplasm pull the rest of the genome.

In *Myoviridae* phages, like T4, some conformational changes occur after attachment of the short fibers to the secondary host receptor. The baseplate reorganizes as it binds to the cell, changing its shape from a hexagon to a star. This conformational change triggers the contraction of the sheath, whose subunits slide over each other and drive the tail tube through the membrane of the host cell, creating a channel for genome transport. The tip of the inner tail tube is the first part to pass through the outer membrane, and then lysozyme molecules from the tail are released to create a passage in the peptidoglycan layer of the cell wall. Finally, the tip of the tail tube also reaches the inner membrane, and a channel is created for dsDNA passage into the cell. Regarding *Siphoviridae*, for instance, SPP1 presents a rotation of the internal domain of the tail during genome ejection, propagating the signal from the tip to the gatekeeper. The tip is released after receptor binding, opening the basal part of the tail, and the TMP exits, allowing DNA to pass. Also in *Podoviridae*, some main conformational changes have been observed related to the position of fiber proteins and the opening of the end of the tail tube.

In addition to injecting DNA into the host cell, many viruses also inject proteins. For instance, T4 injects a protein that modifies host RNA polymerase function, which is not essential for phage infection. T7 bacteriophage injects large proteins of the inner core, which may build channels in the periplasmatic space for the passage of DNA and other proteins. In this case, these core proteins have been described as essential for phage growth.

If we now focus on herpesviruses, the first thing to note is that they do not have a tail machinery, and after the first contact with the host cell their capsid enters it via membrane fusion, a process that leaves it uncoated. The capsid and tegument are then released into the cytoplasm, and it is known that the capsids are transferred via microtubules to the nuclear pores. It is there where genome ejection occurs, with the capsid docked at the nuclear pore and the genome entering the nucleus. This process is largely unknown, but the tegument proteins from the portal vertex tail-like structure may be involved. Some tegument proteins are thought to reach the interior nucleus as well, possibly independently of the genome.

Therefore, the strategy by which herpesviruses release their genomes into the nucleus of the host cell may appear in some aspects analogous to that used by tailed phages to infect cells. Given the endosymbiotic theory, this similarity could reflect the conservation of an ancient infection pathway.

Genome Replication

Once released into the prokaryotic cell or the eukaryotic nucleus, the genome is replicated, usually via the rolling-circle mechanism, which produces a long head-to-tail concatamer. The size of genomes ranges from approximately 15 kbp to 500 kbp, without conserved genomic structure in most cases, this feature being common in only some genera.

There are some exceptions regarding the concatemeric form of genome replication. For instance, $\Phi 29$ replicates its genome in unit-lengths with terminal proteins, P1 phage has a circular genome, λ uses first the θ replication mechanism and the chromosome of Mu is surrounded by bacterial-derived sequences because it is inserted into the host genome and directly cleaved from there and packaged. For some herpesviruses a first phase of θ -type replication has been described to initiate replication before the rolling-circle mechanism starts.

Procapsid Morphogenesis

Procapsids, the precursors of mature capsids, contain no dsDNA and are not icosahedral but spherical. In some cases, they are smaller than mature capsids, although in other cases the volume does not increase upon maturation. Procapsids, also called proheads in the case of tailed phages, contain the portal, the MCP and scaffolding proteins. The interaction between these three components is key for determining the correct shape and size of the procapsid. The assembly process takes place in an ordered manner, with the building of some subassemblies, which are later joined. MCP and scaffolding proteins co-assemble and arrange around the portal protein, which acts as nucleation point or assembly initiator complex. The MCS proteins build a complete shell, devoid of DNA but filled with scaffolding proteins (**Fig. 5(A)**). Inner scaffolding proteins are present inside procapsids before dsDNA encapsidation and they facilitate morphogenesis of the particle, providing stability and preventing enclosure of inappropriate molecules. Some viruses have independent scaffolding proteins, while in others the role of these proteins is performed by a disposable part of the MCP. In many cases, the scaffolding protein is cleaved by proteases also present in the procapsid and expelled after assembly during genome translocation. In the case of some herpesviruses, it has been described that around 1200 copies of the scaffold protein are found on a single procapsid, and 150 of them are an extended form with a N-terminal protease domain. The scaffold protein is cleaved and lost, except for this protease domain, which remains in the mature capsid after DNA is packaged. When present, proteins of the inner core may also be in the procapsid, undertaking a largely unknown role during its morphogenesis but presenting structural changes during maturation.

Fig. 5 *Procapsid morphogenesis and genome packaging.* (A) P23-45 procapsid and expanded capsid (PDB 6IBC and PDB 6I9E). Structures are shown at the same scale. The MCP is depicted in orange and the auxiliary protein in magenta. (B) Large terminase monomeric structures solved by X-ray crystallography. The structure of the T4 phage (PDB 3CPE) corresponds to the complete protein, while nuclease domains are shown in the case of SPP1 phage (PDB 2WC9), HCMV (PDB 3N4Q) and HSV-1 (PDB 4INOX). Structures are depicted with the same orientation, showing the common conserved fold, with α -helices in red, β -strands in yellow and loops in light blue. In the case of SPP1 and HCMV structures manganese atoms are represented in purple.

During capsid maturation, which occurs in parallel to genome packaging, other changes have been described, in addition to the cleavage and release of scaffolding proteins. A reorganization of the MCP domains occurs, with some conformational changes that confer an increase in stability throughout the formation of the mature capsids. MCP domain A is tilted around 20° with respect to domain P, and there is an increase in the sixfold symmetry of hexons. As mentioned before, in some cases there is an overall increase in the head volume, for instance, the diameter of the head of T7 increases by 12%–15% and the head has a thinner and smoother shell with respect to the prohead. As the outline of mature capsids is more symmetrical than those of procapsids, the bonding matrix between intersubunits changes, because the subunits of the MCP move in the plane and also along radial axes, thereby reinforcing ionic and hydrophobic interactions and producing a more stable and angularized capsid. After dsDNA packaging, additional decoration or stabilization proteins may also be added to the shell, further reinforcing it or conferring other properties.

Genome Packaging

Regarding dsDNA packaging, it is an energy-driven process that fills the procapsid with the genome, yielding the final mature capsid. The genome is recognized by the terminase complex, and the terminase-dsDNA complex docks at the procapsid portal vertex. The terminase has ATPase activity, which provides the energy for the translocation of the genome inside the capsid through the portal channel. This machinery is among the most highly energy-demanding described in biology. It has to push dsDNA into a closed space against a genome concentration gradient, exerting a considerable force, reaching 60 pN.

Although terminases provide an example of sequence similarity between tailed phages and herpesviruses, it is not yet clear whether they have different stoichiometries. In bacteriophages, terminases are formed by a small and large subunit: the small subunit binds the DNA and recognizes the specific sites, while the large subunit contains the ATPase and nuclease activity. Available structures show that terminases assemble at the portal vertex, where they form ring-shaped complexes. Phage $\Phi 29$, which is replicated in unit-length genomes with terminal proteins, has only one terminase protein and a packaging RNA (pRNA). In systems where no cut is required, packaging ATPase complex is a more accurate name than terminase, as the terminase complex receives its name because it cuts the DNA after encapsidation of a single unit genome. In herpesviruses, the terminase is a complex comprising at least three proteins. There is little structural information available about the complex, but the crystallographic structure of a nuclease domain of HCMV pUL89 and HSV-1 pUL15 shows an RNaseH/integrase-like fold, whose activity is dependent on manganese ions (Fig. 5(B)).

There are two different mechanisms to ensure that complete genomes are packaged: either specific recognition sites that are recognized by the packaging machinery, or terminally redundant genomes that are packaged with a headful system that fills

capsids with slightly more than one genome. Phages such as λ and herpesviruses employ the first strategy, while P22 and SPP1 use the second one.

Regarding the role of the portal during packaging, it has been suggested that it participates in signaling the end of the translocation. The portal may sense the pressure in the interior of the capsid and transmit this information to the packaging enzymes in order to trigger dsDNA cleavage and detachment of the terminase-dsDNA complex from the portal vertex. Synchronized movements of the wing and clip domains could allow a cross-talk mechanism between the interior and exterior of the capsid. Some portal mutants in SPP1 and P22 present altered chromosome lengths. An additional function of the portal may be the temporary retention of the dsDNA before the tail assembly, as has been described in the case of T7 bacteriophage. T7 portal presents two distinct conformations in its channel valve region, formed by the tunnel loop plus the α -helix protruding into the channel, which is able to bend and tilt 90°. The open state would allow passage of the genome, while the closed state would not. The closed state may serve to seal the capsid once the genome has been packaged and the terminase detached but the tail has not yet been assembled, thereby preventing dsDNA leakage.

As viral genomic translocation has no counterpart in cellular processes, the inhibition of packaging has been highlighted as a target for antiviral therapies.

Final Virion Assembly

When the terminase-dsDNA complex detaches from the portal, the final virions must be assembled, and at this point the process differs between tailed phages and herpesviruses. In bacteriophages, the neck and/or tail proteins bind at the portal vertex, yielding directly the mature virion. It has been proposed that collar, gatekeeper or adapter proteins may participate in the retention of the genome before the incorporation of the whole tail. In the case of *Siphoviridae* and *Myoviridae* like λ and T4, neck proteins assemble first, and then the whole pre-assembled tail binds to them. Tail morphogenesis usually begins with the formation of the initiator complex, which is the distal part of the tail, the tip or baseplate, plus the TMP complex. This substructure initiates the polymerization of the tubular section of the tail around the TMP, in the case of *Siphoviridae* built by the MTP, and in the *Myoviridae* also by the outer contractile sheath. Finally, when the whole TMP is enclosed, the terminator or capping proteins complete the assembly of the tail. The proteins, which stabilize the complex and bind it to the neck, present structural similarity between the two subfamilies. In contrast, *Podoviridae* phages like Φ 29 and P22 use a stepwise addition mechanism of tail components to the prepackaged head. The same occurs for the T7 bacteriophage, for which it has been described how first the dodecameric adapter oligomerizes upon binding to the head portal, and then the hexameric nozzle is assembled, building the tubular end of the tail. Finally, the incorporation of the six trimeric fibers generates the mature virion, which is released to the media after lysis of the bacterial cell.

In the case of herpesviruses, they use a non-lytic mechanism for exiting the infected cell. After genome encapsidation and assembly of some tegument proteins in the nucleus, the envelope is acquired when nucleocapsids bud through cell membranes during the late stages of viral assembly. The origin of the first viral envelope is the inner nuclear membrane, and it is formed immediately after the nucleocapsid and primary tegument are assembled at the nucleus. Afterwards, the particle is de-enveloped upon transit across the outer nuclear membrane. Once in the cytoplasm, the particle enters the Golgi apparatus, where additional tegument proteins are added and the final envelope is acquired by budding into post-Golgi cellular compartments. Finally, virions are released into the media after a reverse endocytosis process.

Conclusions

Structural analysis of the mature virions and viral infection cycles of tailed phages and herpesviruses reveals that, despite the multiple differences between these two viral groups, they share significant characteristics and traits. Given the similarities, it is reasonable to assume that they had a common ancestor a long time ago. Since herpesviruses are now much more uniform than tailed phages, it has been hypothesized that either their architecture represents the ancestral form before evolutionary divergence, or that only one among the various tailed phage types was able to colonize eukaryotic cells. The spectacular advances in structural biology will allow future studies to provide more valuable information that could answer some of the questions remaining.

Glossary

Cryo-electron microscopy Technique allowing to image macromolecular structures in frozen-hydrated conditions with a transmission electron microscope. Images obtained can be combined via image processing and reconstruction algorithms to produce a three-dimensional map of the object.

Double jelly roll Protein fold formed by two β -barrels. In adenoviruses and structurally related viruses, the β -barrels are perpendicular to the capsid surface. Double jelly roll capsid proteins form pseudo-hexagonal capsomers, allowing trimeric proteins to fill in the six-fold coordinated positions of the icosahedral capsid.

Four-helix bundle Protein fold consisting of four α -helices coiled together with a hydrophobic core in the center.

Icosahedral asymmetric unit The minimal part of an icosahedral object which contains enough information to

build the complete object by repetition following the icosahedral symmetry transformations. There are 60 asymmetric units per icosahedron.

Polintons Eukaryotic dsDNA transposons encoding a protein-primed DNA polymerase (POL) and a retroviral-like integrase (INT).

Structural lineage A group of viruses which share common structural elements and assembly principles.

β -barrel fold Protein fold consisting of eight antiparallel β -strands organized in two sheets that form the opposite sides of the barrel.

β -helix Protein fold consisting of parallel β -strands in a solenoid pattern, usually with three faces.

β -spiral Protein fold consisting of repetitions of two anti-parallel β -strands connected by a β -turn.

General Features of Adenoviruses

Adenoviruses were discovered in 1953 in human adenoid tissue, and since then have been found in all types of vertebrates, from fish to humans. They are currently grouped in five genera. Mastadenoviruses and aviadenoviruses infect mammals and birds, respectively. So far only a single member of the Ichtadenovirus genus has been reported, isolated from white sturgeon. The other two genera have broader host ranges. Atadenoviruses have been found in reptiles, ruminants, and birds, and siadenoviruses in amphibians, birds, and reptiles. More than 80 different human adenovirus types have been reported, causing mainly mild respiratory, gastrointestinal, and ocular diseases. Adenoviruses are also widely used as experimental vectors for gene transfer, vaccination, and oncolysis.

Adenoviruses have a linear, dsDNA genome packed within a non-enveloped icosahedral capsid of 95 nm diameter and triangulation number $pseudoT = 25$. The virion has a mass of 150 MDa and presents a complex protein composition (**Fig. 1(a)**). The major coat protein, hexon, forms most of the icosahedral shell. Penton capsomers (formed by penton base and fiber) sit at the vertices. At least three different minor coat proteins (IIIa, VI, VIII) are required to complete the icosahedral shell, and more are present in some genera. To describe the complex adenovirus structure, it is useful to consider some geometrical landmarks. Each capsid facet is formed by 12 hexon trimers. Four hexon trimers, plus one penton base monomer, form the icosahedral asymmetric unit (AU). Nine hexon trimers form the central plate of each facet or GON ("Group of Nine"). The group formed by five peripentonal hexon trimers, together with the penton base, has been designed as GOS ("Group of Six") (**Fig. 1(b)**). Inside the capsid, the adenovirus genome is bound to a large amount of positively charged, virus encoded proteins, forming the so-called core, which does not follow icosahedral symmetry (**Fig. 1(c)**). Genome length varies between adenovirus genera, ranging from 26 to 45 kbp.

Structure of Human Adenovirus Type 5

For historical reasons and because of its extended use in the viral vector field, human adenovirus type 5 (HAdV-C5) is the best characterized member of the adenovirus family. The structure of the HAdV-C5 virion was solved by cryo-electron microscopy (cryo-EM) at 3.5 Å resolution in 2010, in an impressive achievement given the size and complexity of the viral particle. The structure has been improved to 3.2 Å resolution in 2017, showing clearer details for some of the minor proteins.

Hexon

Hexon (also called polypeptide II in early literature) is the main building block in the icosahedral shell. There are 720 hexon monomers (forming 240 trimers) in the icosahedral particle. The 952 residue-long monomer contains two eight-stranded β barrels V1 and V2 (also called jellyroll domains) which in the virion are oriented perpendicularly to the capsid surface. A small β -sheet Vc (connector domain) holds the two barrels apart (**Fig. 2(a)**). The jelly roll domains form the hexon trimer pseudo-hexagonal base, which occupies the 6-fold coordinated positions in the icosahedral shell. Long loops connecting the β -strands form the hexon towers, which appear as triangular-shaped protrusions on the capsid surface. Some of the loops correspond to the so-called hypervariable regions, involved in defining the specific serological response to the virus. In the trimer, the three hexon monomers are heavily intertwined, resulting in a highly stable molecule. The amino and carboxy terminal regions adopt different conformations in each monomer, facilitating the hexon interactions with its neighboring proteins in the different capsid environments.

Penton Base

The penton base protein, or polypeptide III, occupies the 5-fold coordinated positions in the icosahedral network. There are 12 penton base pentamers in the capsid, one in each vertex.

The 571 amino acid-long penton base monomer folds into two domains: a single jellyroll perpendicular to the capsid surface, completing the spaces left by hexons in the shell, and an upper insertion facing the solvent exposed exterior (**Fig. 2(b)**). This upper domain contains an Arg-Gly-Asp sequence motif, needed to interact with cell integrins for viral internalization during infection. This motif forms part of a long (80 residues), flexible loop which could not be resolved in the structure. For each penton base monomer, an N-terminal arm (residues 37–51) extends away from the main body of the protein towards the viral core, interacting with two monomers of the inner coat protein IIIa (see below), and therefore contributing to anchor the penton within the surrounding hexons in the GOS. Regulation of penton stability is crucial during the infectious cycle. Pentons are the first elements to dissociate from the capsid under stress, and it is thought that their release at the initial stages of uncoating opens the way for the adenovirus membrane lytic peptide to exit the capsid, and disrupt the endosomal membrane. In this way, the virus particle can travel along the microtubular network and reach the nuclear pore, where it will release its genome for transcription and replication.

Fiber

Adenovirus fiber, or polypeptide IV, is responsible for host receptor recognition. One trimer of the 582 residue long fiber is bound to each pentamer of penton base at the vertices. Because of this symmetry mismatch, and because fibers are flexible, they have not been clearly visualized in cryo-EM structures of the complete virion, which use icosahedral averaging. The available fiber structures have been obtained from the analysis of recombinant protein fragments. Each fiber contains an amino-terminal penton base attachment domain; a long, thin central shaft; and a carboxy-terminal head (or knob) domain (**Fig. 2(c)**). A crystal structure of recombinant penton base bound to the N-terminal fiber peptide showed a 10-residue long fiber fragment bound at the cleft formed by two adjacent penton monomers. In the crystal, all five clefts were occupied by the fiber peptide. In the virion, there are only three fiber monomers per vertex. It is not known what mechanism decides which three of the five available binding clefts in penton base are used to bind fiber.

Beyond the N-terminal tails, the shaft extends away from the capsid surface and ends at the head domain. The sequence of the shaft domain consists of several repetitions of a 15-residue sequence motif. Each one of the repeats forms two anti-parallel

Fig. 1 Overall adenovirus structure and components, as exemplified by current knowledge on human adenovirus structure. (a) Icosahedral shell organization. The left hand side panel is a model built from a low resolution cryoEM map, with penton bases highlighted in yellow, and fibers built from the crystal structure of the knob and distal shaft (PDB ID 1QIU) in dark blue. The shaded triangle indicates one facet. The right hand side is a cartoon representing the location of major and minor coat proteins forming the icosahedral shell, as indicated by the adjacent legend. Each hexon trimer is depicted as a hexagon with an overlaid triangle indicating the position of the towers. (b) Geometrical landmarks in the adenovirus icosahedral net. One penton and the five adjacent facets are represented, spread out for clarity. The four hexon trimers forming the asymmetric unit (AU) are numbered in one facet. Peripentonal hexons, forming the Group of Six (GOS) together with the penton, are highlighted in yellow. Hexons in the Groups of Nine (GON) are depicted in white for the reference facet, gray in the rest. Red symbols indicate the icosahedral symmetry axes. (c) Non-icosahedral components. A segment has been removed from the cryoEM map to show the inner capsid contents. The schematics on the right hand side indicate tentative positions, as little is known about the structure and organization of the genome and accompanying proteins in the virion. A small fragment of protein VII has recently been identified in the icosahedral shell (see main text, and **Fig. 3**). Figure modified from San Martín, C., 2012. Latest insights on adenovirus structure and assembly. *Viruses* 4, 847–877.

Fig. 2 High resolution structures of HAdV-C5 capsid proteins. (a) The hexon trimer is depicted in a ribbon representation, with each monomer in a different color, in side, top (as seen from outside the capsid) and bottom (from inside) views. The two vertical jelly rolls in one monomer are labeled (V1 and V2). A β -sheet that separates them is labeled Vc (for Viral Connector domain). The amino (Nt) and carboxy (Ct) termini of one monomer are indicated. (b) The penton base pentamer depicted in side and top views. Each monomer is rendered in a different color. The position of the disordered loop containing the integrin binding Arg-Gly-Asp sequence motif, as well as the amino (Nt) and carboxy (Ct) termini of one monomer, are indicated. (c) Structure of the vertex complex, composed by the pentameric penton base and the trimeric fiber. The fiber knob and distal shaft structures solved by protein crystallography are shown in the left hand side zoom, with each monomer in a different color. A simple model of the fiber shaft has been generated by drawing 20 shifted copies of one shaft repeat. Three N-terminal fiber peptides (red) are shown, bound to the penton base pentamer (gray). Center: side view; right, oblique view. The protein databank identifiers for the structures depicted here are: 1QIU for the fiber and shaft, 3IZO for the N-terminal fiber peptides, 6B1T for hexon and penton.

β -strands connected by a β -turn, in a fold known as β -spiral. The β -strands are oriented along the fiber axis, and each repeat represents a rise of 13 Å in the fiber length. The HAdV-C5 fiber shaft contains 22 such repeats, resulting in a 330 Å long fiber (including the ~45 Å tall head). A breakdown of the consensus sequence in the third repeat causes a kink in the shaft. The average diameter of the shaft, excluding the surface loops, is 15 Å. At the C-terminal end of the shaft we find the knob domain, responsible for attachment to the adenovirus receptor at the host cell membrane. The head domain in each fiber monomer folds as an anti-parallel β -sandwich formed by two four-stranded sheets. Loops connecting the β -strands are exposed on the surface of the trimeric fiber head, available to bind the cell receptor.

Minor Coat Proteins

Apart from hexons and pentons, the HAdV-C5 virion contains four minor coat proteins: IIIa, VI, and VIII on the inner capsid surface (Fig. 3(a)), and protein IX on the outer one (Fig. 3(b)).

Protein IIIa

Five copies of protein IIIa (585 amino acids) are located beneath each vertex (Fig. 3(a)). The structure of a region comprising residues 7–300 has been solved, while the rest of the polypeptide chain (residues 300–585) is not icosahedrally ordered, and thus remains unresolved. The IIIa fold is predominantly α -helical. The N-terminal domain, or GOS-glue domain, helps stabilize the GOS by bridging every penton to its surrounding hexons. This domain is linked by a long helix to another region (“VIII-binding domain”) which interacts with another minor coat protein, polypeptide VIII, joining the GOS to the hexons in the central plate of the facet (GON). The unresolved C-terminal region may be interacting with the non-icosahedral core. Apart from stabilizing the vertices, protein IIIa contributes to the specificity of genome packaging via interactions with one of the adenovirus packaging proteins, L1 52/55 kDa.

Protein VI

Polypeptide VI is synthesized as a 250 residue long precursor (pVI) and cleaved at two sites by the adenovirus protease during maturation: between residues 33 and 34 at the N-terminus, and 239–240 at the C-terminus. There are approximately 360 copies of protein VI in the virion. This protein binds to hexon and to dsDNA, bridging capsid and core. Only two fragments of pVI have been solved in cryo-EM studies of the virion (Fig. 3(a), inset). The cleaved N-terminal peptide (residues 5–33) lines the wall of the hexon trimer cavity that opens towards the core. Another segment, comprising residues 109–143, crosses the opening of the cavity. Only three copies of the N-terminal peptide and one of the central fragment have been traced in the AU, indicating that most of the protein is not ordered. The hexon:VI stoichiometry is also uncertain. There are too many copies of VI (360) to have one per hexon trimer (240), but not enough to have one per hexon monomer (720). Protein VI carries out multiple functions during the adenovirus infectious cycle. It acts as a shuttle to transport newly synthesized hexons to the nucleus for assembly; its C-terminal peptide is a cofactor required to activate the maturation protease; and it contains the adenovirus lytic peptide, an amphipathic helix (residues 34–54) that alters the curvature of the endosome membrane, so that the virus can escape into the cytosol during entry. After internalization, protein VI needs to be released from its internal position in the capsid for the lytic activity to take place.

Protein VIII

The precursor form of protein VIII (pVIII, 227 amino acids) is cleaved by the viral protease during maturation at residues 112, 131, and 157. The larger fragments (residues 2–112 and 157–227) stay together and ordered in the virion. The 45 central residues have not been identified in the cryo-EM HAdV-C5 studies, indicating that they are either removed upon proteolytic processing, or disordered. There are two independent monomers of polypeptide VIII in the AU. One of them is wedged between protein IIIa and the hexons at the periphery of the GOS, cooperating with IIIa to bind each GOS to its five surrounding GONs. The second copy is located around the icosahedral 3-fold symmetry axis, contributing with polypeptide IX (see below) to the stabilization of each GON (Fig. 3(a)). Each copy of VIII interacts with four hexon trimers. Interestingly, some of these interactions occur by β -sheet augmentation. That is, the interaction is mediated by a β -strand from polypeptide VIII binding to the edge of a β -sheet in hexon.

Protein IX

Polypeptide IX is the only minor coat protein located on the outer surface of the HAdV-C5 capsid (Fig. 3(b)). This 140 amino acid long polypeptide has a remarkable extended conformation, reaching 185 Å in length. The amino- and carboxy-terminal domains are connected by a central “rope domain” with little secondary structure. The amino-terminal domains of three IX monomers join via hydrophobic interactions at the icosahedral and local 3-fold axes in the GONs, forming a triskelion-shaped structure (four triskelions per facet). The rope domain of each monomer forming the triskelion runs in a different direction towards the facet edges. There, the C-terminal α -helices of four IX monomers join to create a 4-helix bundle. Three of the helices in the bundle are parallel and belong to IX monomers forming different triskelions in the same facet. The fourth is antiparallel, coming from a copy of IX in the adjacent facet (Figs. 3(b) and 5(b)). The 240 copies of protein IX form a sort of hairnet on the virion surface, keeping the hexons in each GON together and binding GONs to neighboring GONs across the icosahedral edges. Protein IX is dispensable for adenovirus assembly, but IX-deletion mutants assemble viral particles with low thermostability. The triskelion N-terminal domain of IX is enough to confer capsid thermostability. Protein IX has also been proposed to participate in the final stages of uncoating during adenovirus entry. After

Fig. 3 Structure of the complete HAdV-C5 icosahedral asymmetric unit. The proteins in one AU and their closest neighbors are depicted as ribbons as seen from inside (a) and outside (b) the virion. Proteins are colored according to the legend at the bottom left. The four hexon trimers in the AU are numbered 1–4 as in Fig. 1(b). A pentagon, a triangle and an oval indicate the positions of the icosahedral 5-fold, 3-fold and 2-fold axes respectively. The inset in (a) shows a zoom in the hexon 2 region, where fragments of protein VI and VII are traced. Dashed purple lines in (b) indicate the path followed by disordered regions of protein IX. The dashed arrow indicates where a monomer of IX would continue towards the other side of the icosahedral facet. The structure depicted corresponds to protein databank entry 6B1T.

escaping from the endosome, adenovirus particles travel along the microtubule network towards the nuclear pore, to release the viral genome into the nucleus. Capsids are anchored to the nuclear pore complex via hexon, while simultaneously being pulled away by microtubule motor kinesin-1 which binds to protein IX, resulting in capsid dismantling. However, mutants lacking IX are still infectious, so alternative mechanisms must exist to complete capsid disassembly.

Core Proteins

The HAdV-C5 genome is organized within the capsid in a nucleoprotein core composed by a 35 kbp long, linear dsDNA molecule, bound to over 20 MDa of viral proteins (Fig. 1(c)). The copy number of the proteins present in the core is not well defined, as different estimations have been reported. Core proteins V (366 amino acids, 150 copies), VII (198 amino acids, 500–800 copies), and μ (also called X, 80 amino acids, 100–300 copies) have a large amount of positive charges and are thought to condense the viral genome by compensating for the electrostatic repulsion between the negative charges of the dsDNA molecule.

Protein V has a theoretical isoelectric point (pI) of 10.3. It interacts with penton base and minor coat protein VI, and part of it is released in the endosome during the first stages of uncoating. It seems therefore that protein V is located at the outermost layers of the core, bridging it to the capsid. *Protein VII* (pI 12.3) is the mature form of polypeptide pVII, resulting from cleavage by the maturation protease at residues 13 and 24. Polypeptide VII participates in virus assembly by interacting with packaging proteins IVa2 and L1 52/55 kDa. However, particles without protein VII can be assembled, although they are not infectious. One of the pVII segments cleaved by the protease (residues 14–24) occupies a position equivalent to that of the cleaved N-terminal peptide of minor coat protein VI, lining the hexon cavity wall (Fig. 3(a), inset). *Protein μ* (pI 12.9) is also synthesized as a precursor form, cleaved by the maturation protease at residues 32 and 51. It has been suggested that μ helps condense DNA in the virus core acting as a bridge between DNA strands.

Because the core does not follow icosahedral symmetry, its architecture has not been elucidated in high resolution cryo-EM studies, and structural data for the individual proteins are scarce. When the nucleoprotein complex is extracted from the virion, objects consistent with a “beads-on-a-string” organization are observed, supporting the idea that core proteins condense the genome by a strategy similar to that of histones. Protein VII, the most abundant core protein, remains bound to the genome in the beaded structure even after harsh chemical treatment. It is therefore thought that protein VII wraps the dsDNA to form the 9.5 nm diameter nucleosome-like beads. Cryo-electron tomography analyses allow observing the core in individual virus particles without imposing icosahedral symmetry, but so far the resolution they provide has been limited. A physical model for the core organization proposed that the organization of DNA and associated proteins is ruled by a soft electrostatic repulsive potential. This model is consistent with the fact that the positive charges of all the core proteins are not enough to compensate for all the negative charges provided by the dsDNA.

Also bound to the HAdV-C5 genome in the core are the terminal protein and the maturation protease. The terminal protein is involved in initiation of genome replication, and one copy remains bound to the 5' termini of the dsDNA molecule in the infectious particle. The maturation protease enters the particle bound to the genome in a largely inactive form. After the protease cleaves pVI, the carboxy-terminal released peptide (pVIC) remains covalently bound to the enzyme and enables it to slide on the dsDNA molecule to reach all its targets. These include: minor coat proteins IIIa, VI and VIII, core proteins VII and μ , the terminal protein, and the packaging protein L1 52–55 kDa. Proteolytic maturation makes the HAdV-C5 particle metastable, priming it to start the programmed uncoating cascade, release the lytic peptide in the endosome, and the genome at the nuclear pore. Particles deficient in maturation are not infectious, remain trapped in the endosome and are destroyed further along the endocytic pathway.

Variants: Other Adenoviruses

Structural studies on the complete virion are available for only two of the five adenovirus genera: mastadenoviruses, and atadenoviruses. Mastadenoviruses infect mammals and include the human adenoviruses (HAdV), classified into seven species (A to G). High resolution cryo-EM structures are available for HAdV-C5 (3.2 Å resolution) and HAdV-D26 (3.7 Å). Structural characterization of non-human mastadenoviruses is limited to bovine (BAdV-3) incomplete capsids at high resolution (4.5 Å) and medium resolution structures of bat (BtAdV-250A) (13.7 Å) and canine (CAdV-2) (12 Å) adenovirus. As for atadenoviruses, two medium resolution structures are available: ovine adenovirus OAdV-7 (10.6 Å) and snake adenovirus SnAdV-1 (10.9 Å). The latter is the only structure for an adenovirus infecting non-mammalian hosts analyzed so far. Overall, structural studies demonstrate that all adenoviruses share a common general organization of the virion, yet certain differences are noteworthy as they might have relevance in features such as structural stability or tropism. The main differences observed concern the structure and number of fibers, and the minor coat proteins on the outer capsid surface.

Fiber Shafts and Heads

The main tropism determinant in adenovirus is the fiber-penton base complex. A considerable number of fiber head structures are available, obtained from recombinant proteins. All adenovirus fibers described so far are trimeric, with an N-terminal tail, a central shaft made of repeating sequences, and a C-terminal globular knob domain as in HAdV-C5. Although the main structural features are conserved, fiber sequences vary considerably between adenovirus types, reflecting the ability to bind different receptors for reaching different target tissues.

Fig. 4 Variations in the structure of adenovirus fiber heads. (a) Phylogenetic tree of adenovirus fiber head domains based on structural comparison. A total of 11 fiber head structures are compared, with protein data bank identifiers as follows. Human adenoviruses: HAdV-C2 (1QHV); HAdV-C5 (1KNB); HAdV-A12 (1KAC); HAdV-B11 (2O39); HAdV-B3 (1H7Z); HAdV-D37 (1UXE); HAdV-D19p (1UXB); HAdV-F41s short fiber head (2BZV). Non-human adenoviruses: canine adenovirus CAAdV-A2 (2J2J); fowl adenovirus FAdV-A1l long fiber head (2IUM); and FAdV-A1s short fiber head (2VTW). Capital letters by the tree branches refer to the human adenovirus species A-F. Red lines (branches) and circles (nodes) highlight the relationship between canine, enteric and avian adenovirus fiber heads. (b) Structure of a siadenovirus fiber head, highlighting the unique β -hairpin that embraces the neighboring subunit in the trimer. The structure depicted corresponds to the turkey adenovirus type 3 (also known as turkey hemorrhagic enteritis virus, THEV) protein (PDB: 3ZPF). The carboxy (Ct) terminus of one monomer is indicated. (a) Figure modified from El Bakkouri, M., Seiradake, E., Cusack, S., Ruigrok, R.W., Schoehn, G., 2008. Structure of the C-terminal head domain of the fowl adenovirus type 1 short fibre. *Virology* 378 (1), 169–176, with permission from Elsevier.

In human adenoviruses, the first 45 residues of the fiber protein correspond to the penton binding tail, and are highly conserved (typically over 50% identity with the HAdV-C5 prototype). The rest of the protein (central shaft and knob domain), however, differs in key structural and chemical features. The number of repeats in the shaft determines the fiber length, and disruptions in the repeat sequence determine the location of kinks in the otherwise rigid fibers. Fiber lengths in human adenoviruses range from 130 Å (300–350 amino acids, 5–7 repeats) in species B, to more than 300 Å (500–600 amino acids, over 20 repeats) in species C and A. Fibers in human adenovirus species B and D lack the 2- to 4- residue insertion that disrupts the repeating sequences of the shaft, resulting in rigid fibers. Notably, the fiber of bovine BAdV-3 is extremely long (976 amino acids). Fiber head surface charge plays a role in the selectivity of the different receptors in the cell membrane. For example, members of species C tend to have negatively charged fiber heads ($pI \sim 5$) and use the membrane protein CAR as a receptor, while most members of species D have positively charged fiber heads ($pI \sim 9$) and bind sialic acid. Most adenovirus fiber heads engage their receptors with lateral interactions, usually involving two monomers of the head per receptor, and binding 3 receptor molecules per fiber trimer. However, frontal interactions have recently been reported for HAdV-B3, with asymmetric interactions (either one or two receptors per fiber trimer).

Apart from shaft length, fibers may also vary in numbers. Human adenoviruses belonging to species F (HAdV-F40 and HAdV-F41), that show enteric tropism, have two fiber genes of different length, but only incorporate one fiber per vertex, either a long or a short one. All known aviadenoviruses have two fibers per vertex. Fowl adenovirus type A (FAdV-A) has two fiber genes of different length, whereas two fiber genes of equal length are found in FAdV-C. FAdV-B, FAdV-D, and FAdV-E contain just one fiber gene. Structure and sequence alignments suggest that, among human adenoviruses, HAdV-F41 is the closest to the animal viruses. In fact, in phylogenetic trees calculated from such alignments, the HAdV-F41 short fiber head appears closer to the avian fiber heads than the canine adenovirus fiber head (Fig. 4(a)). In the Atadenovirus genus, ovine (OAdV-7) and snake (SnAdV-1) adenoviruses have only one fiber gene and present only one fiber per vertex. However, in a lizard atadenovirus (LAdV-2), two fiber genes were found. Interestingly, the two different fiber proteins assemble as either one short or three long fiber projections per

vertex (present in one or two vertices per virion). Overall, fiber heads in atadenoviruses are smaller (107 amino acids in SnAdV-1; 123 and 120 amino acids in LAdV-2) than in mastadenoviruses (183 amino acids for HAdV-C5) and aviadenoviruses (248 and 209 amino acids for the two FAdV-A1 fibers). Finally, only one fiber gene has been found in the siadenoviruses studied so far. Siadenovirus fiber heads have two distinctive features. First, their closest structural homologs are reovirus fiber heads, rather than those of other adenoviruses. Second, an insertion in one of the β -strands creates a β -hairpin that embraces the neighboring monomer, a unique feature among all adenovirus fiber heads characterized so far (Fig. 4(b)).

External Minor Coat Proteins

Protein IX, the only minor coat protein located on the outer surface of the HAdV-C5 capsid, is unique to mastadenoviruses. Even within the mastadenoviruses, polypeptide IX considerably varies between the different virus types. In particular, the central region defined in the cryo-EM structure of HAdV-C5 as the rope domain is conserved only among human and simian adenoviruses (Fig. 5(a)). Canine (CAdV-1), bovine (BAdV-3) and bat (BtAdV-250A) adenoviruses have a shorter IX protein lacking this rope domain. This results in the carboxy-terminal helical bundle of IX being located directly on top of the N-terminal triskelions, instead of at a distance at the facet edges as in HAdV-C5. In human adenoviruses the bundle is formed by four helices, three of them belonging to monomers of protein IX forming three different triskelions in one icosahedral facet, and the fourth one coming from a copy of protein IX in the adjacent facet, assembling in an antiparallel fashion to the other three. In non-human adenoviruses the organization is simpler, and the IX monomers do not reach across different AUs or facets: the bundle is formed by just the three helices corresponding to the IX molecules forming the triskelion located directly below (Fig. 5(b)).

In atadenovirus capsids, a genus specific protein called LH3 has been found at the icosahedral and local three-fold axes, the same location occupied by IX in mastadenoviruses. LH3 (~380 amino acids) is twice the size of protein IX (140 residues) and forms prominent knobs on the surface of the capsid, interacting with the towers of three surrounding hexon trimers (Fig. 6). Remarkably, protein LH3 has a trimeric β -helix fold typical of bacteriophage tailspikes, very different from the helix clusters observed in protein IX. The extensive interaction between LH3 and hexons may have a role in the higher capsid stability of atadenoviruses, that can withstand temperatures at which HAdV-C5 particles are completely disrupted (over 48°C). Because bacteriophage tailspikes are responsible for virus attachment to the host, and LH3 configures the outermost surface of the atadenovirus shell, it has been hypothesized that, apart from a cementing function, LH3 may have some role in interaction with the host.

Adenovirus Structural Relatives

During the last two decades, structural biology analyses have shown that viruses infecting hosts far apart in evolution share similar architectural features, prompting a new virus classification based on *structural lineages*. Four icosahedral virus structural lineages are recognized at present. Viruses included in one of these lineages share their major coat protein (MCP) fold with adenovirus.

The Double Jelly Roll Lineage

For a long time, adenovirus was the only known virus where the six-fold coordinated positions in the capsid were occupied by trimers of a major coat protein folding as a double jelly roll perpendicular to the capsid surface. In 1999, the structure of the MCP of a tailless bacteriophage called PRD1 (a tectivirus) was solved, surprisingly showing the same kind of fold and trimeric oligomerization. This finding demonstrated that viruses with none or little sequence homology, infecting very different hosts (human and bacteria), use the same kind of architectural solution to build their capsids, and inspired the idea of classifying viruses on the basis of their MCP structure.

The structural lineage including adenovirus is variously referred to as the PRD1-adenovirus lineage (for its first two described members), the PRD1-like lineage, or the double jelly roll (DJR) lineage. Since the discovery of the same fold in adenovirus and PRD1, dsDNA viruses belonging to 11 different families have been shown to share this MCP fold (*Corticoviridae*, *Iridoviridae*, *Lavidaviridae*, *Marseilleviridae*, *Mimiviridae*, *Phycodnaviridae*, *Poxviridae*, *Sphaerolipoviridae*, *Tectiviridae*, and *Turriviridae*), as well as other unclassified viruses (Table 1). Members of the DJR lineage infect organisms across the evolutionary tree: bacteria (tequiviruses, corticoviruses); archaea (turriviruses); unicellular animals (giant viruses like mimivirus and their relatives, also their virophages) and algae (phycodnaviruses); insects, fish, amphibians, and reptiles (iridoviruses); and vertebrates in general including humans (adenoviruses). The infectious particles of these viruses have a wide range of sizes and triangulation numbers (Table 1 and Fig. 7), but they are all built from trimeric DJR capsomers. It is notable that poxviruses, which do not have an icosahedral capsid, also encode a trimeric DJR protein called D13. D13 is not present in the mature poxvirus particle, but is required for assembly, and its structure suggests that poxviruses may have evolved from an icosahedral ancestor.

Variants of the Double Jelly Roll Fold: PRD1-Like Viruses With Authentic Hexameric Capsomers (Paired Orthogonal Single Jelly Rolls)

The double β -barrel fold is likely to have arisen through gene duplication. In line with this hypothesis is the recent identification of PRD1-like viruses that have two MCPs instead of one, for example bacteriophage P23-77 and several archaea viruses: *Haloarcula californiae* icosahedral virus 1 (HHIV-1), *Haloarcula hispanica* icosahedral virus 2 (HHIV-2), and its close relative virus SH1. In these

viruses the two MCPs (called VP4 and VP7 in the archaea viruses) are morphologically distinct. VP4 is composed of two vertical single jelly rolls, one standing on top of the other. One of the jelly rolls forms the capsomer base, while the other forms the tower. VP7 consists of only one vertical single jelly roll. These proteins share a high structural homology despite their low sequence identity (<20%) with the individual barrels of the double β -barrel MCP of *Pseudoalteromonas* phage PM2, which has the simplest DJR protein of the PRD1-adenovirus lineage (Fig. 7). VP4 and VP7 are ordered in heterodimers which produce two morphologically distinct capsomers, one with two and the other with three towers. The three-tower capsomers are composed of three copies of VP4 and three copies of VP7. The two-tower capsomers are composed of two copies of VP4 and four copies of VP7. The relative orientation of the individual β -barrels in the VP7-VP4 heterodimer anticipates that of the double β -barrel arrangement in PM2. On the basis of common structural and assembly principles, it has been proposed that single vertical β -barrel viruses should be grouped together with the double β -barrel viruses into a vertical β -barrel superlineage. Such a superlineage would include all viruses that use similar virion architecture regardless of whether the hexagonal capsomers are composed of six monomers or three dimers.

Vertex Structures in the Double Jelly Roll Lineage

Apart from the major coat protein which forms most of the capsid, members of the DJR lineage have also a single perpendicular jelly roll protein forming the pentameric vertex capsomers (pentons). The PRD1 penton is essentially a simplified version of the MCP, consisting of a single minimal jelly-roll. In adenovirus, the penton base protein possesses a PRD1-like lower core, adorned with an elaborate upper domain, rich in long loops (Fig. 2(b)). Penton proteins have been found in all PRD1-like viruses for which high-resolution structural information is available, including corticovirus PM2, archaeal turrevirus STIV (*Sulfolobus* turreted icosahedral virus), and virophage Sputnik. Thus far, an equivalent of the penton protein has not been identified among the Megavirales, except for phycodnaviruses (PBCV-1). However, considering the importance of this protein for the formation of icosahedral virions, it is expected that these giant viruses also encode a penton homolog.

Viruses of the DJR lineage tend to possess spikes protruding from the vertices, with a variety of sizes and shapes (Fig. 8). Similarly to the adenovirus fiber, these spikes have been shown to be involved in host recognition and attachment for some of the PRD1-like characterized viruses. As in adenovirus, spikes are often flexible or assemble via a symmetry mismatch on the penton, making their detailed structural characterization much more difficult. PRD1 has two different spikes (proteins P2 and P5) attached to a single pentamer of the vertex protein P31 (penton). Moreover, in PRD1 each spike has a different oligomerization state. P5 is a trimer resembling the structure of the adenovirus fiber, while P2 is a monomer with a pseudo- β propeller head. Sequence similarity and low resolution structural analyses suggest that the N-terminal domain of P5 could be embedded in the capsid by forming a heteropentameric base with P31. The role of each spike in PRD1 host recognition and attachment is not fully known.

It is notable that a trimeric spike attached to a pentameric base is also observed for the dsRNA reovirus attachment protein, $\sigma 1$. What is more, $\sigma 1$ is composed of a filamentous N-terminal tail and a globular C-terminal head folding as a compact β -barrel, with topology identical to the adenovirus fiber head. This observation points to a distant evolutionary relationship between the two proteins, nowadays coded by virus genomes with no other similarity.

Membranes and Membrane Proteins

Most members of the DJR lineage have an internal membrane, except adenovirus and the virophages Sputnik and Mavirus. The internal membrane forms a vesicle that contains the virus genome. Membrane proteins connect the lipid bilayer to the capsid, altering its curvature to follow the icosahedral contours of the shell. In the largest members of the lineage such as mimiviruses, multiple layers of proteins and membranes may exist. Internal membranes seem to be important for different aspects of the infectious cycle, such as genome delivery or assembly. In PRD1, the membrane remodels into a proteo-lipid tube that provides a conduit for passage of the ejected linear dsDNA through the cell envelope. A similar structure has been observed in PBCV-1, where a membrane tunnel is generated by fusion of the virus internal membrane with the host membrane. In Mimivirus, the

Fig. 5 Differences in external minor coat proteins between mastadenoviruses. (a) Alignment of representative polypeptide IX sequences for different species in the Mastadenovirus genus. The extent of the N-terminal (N), rope (r) and helical (H) domains from the HAdV-C5 structure are indicated with letters colored according to the ribbon depiction of the protein shown at the top. Notice that the rope domain is conserved only in human and simian viruses (sequences within a black rectangle). (b) Comparison of protein IX organization in human and non-human mastadenovirus capsids. Left: capsid organization based on the cryo-electron microscopy structures of human adenovirus HAdV-D26 (PDB: 5TX1) and bovine adenovirus BAdV-3 (PDB: 3ZIF). Penton base and fibers are shown in magenta and gold, while the 4 hexon trimers in the AU are colored blue, pink, green, and khaki, respectively. Hexon trimers in one of the asymmetric units are represented as hexagons and labeled 1–4 as in Fig. 1(b). One hexon from a neighboring AU is labeled 2'. A schematic of the icosahedron edges is shown as yellow rods. Right: magnified view of a single facet of the capsid with hexons and internal minor coat proteins hidden to visualize the two different protein IX organizations. The four structurally distinct IX molecules in each AU are colored blue, light blue, cyan, and purple, respectively. In HAdV-D26, only one of the four independent copies of IX (cyan) could be traced in its entirety. Disordered regions which could not be traced are depicted as red lines. In both viruses the triskelions can be seen at both the local and icosahedral 3-fold symmetry axes, identified by red and orange triangles, respectively. While the tetrameric helical bundles in HAdV-D26 are located at the facet edges (light gray filled ovals), the trimeric bundles in BAdV-3 are positioned directly on top of the triskelions. Panel (a) modified from San Martín, C., 2012. Latest insights on adenovirus structure and assembly. *Viruses* 4, 847–877. Panel (b) modified from Matteson, N.L., Barry, M.A., Reddy, V.S., 2018. Structure-based assessment of protein-protein interactions and accessibility of protein IX in adenoviruses with implications for antigen display. *Virology* 516, 102–107, with permission from Elsevier.

Fig. 6 External minor coat protein in atadenoviruses. Top left: the cryo-EM map of snake adenovirus type 1 is shown in gray, with the genus specific minor coat protein LH3 highlighted in gold. Top bottom: the crystal structure of LH3 (gold, PDB: 5G5N) and its position with respect to hexons (modeled by homology with the HAdV-C5 hexon as template, gray) is shown in a view across the particle. Bacteriophage P22 capsid (EMD-8005) with the tailspike protein in blue (PDB: 1TSP) is shown at the right hand side for comparison. The SnAdV-1 cryo-EM map identifier at the electron microscopy databank is EMD-3599.

internal membrane fuses with the host endocytic vacuole to release the viral genome to the cytoplasm. For the marine bacteriophage PM2, it has been proposed that membrane proteins may play a scaffolding role, recruiting capsid proteins to the lipid bilayer during assembly.

Genomes in the Double Jelly Roll Lineage

Most members of the DJR lineage have a dsDNA genome, either linear (PRD1, Mimivirus, adenovirus) or circular (PM2, STIV, Sputnik). The only known exception so far is the *Flavobacterium* phage FLiP, with a circular ssDNA genome. A characteristic of DJR viruses infecting eukaryotic hosts (adenovirus, PBCV-1, poxviruses, asfarviruses) is the encoding of positively-charged, histone-like proteins that are packaged together with the genome. These proteins condense the dsDNA and also play a role in protecting the virus genome from the host defense machinery from entry to replication. In the algae virus PBCV-1, the capsid remains outside the cell while the viral genome is injected. This genome has to reach the nucleus to start the first replication phase. It has been observed that the PBCV-1 genome is translocated as a condensed structure. This form would facilitate its trafficking in the dense cytoplasm milieu by facilitating the bypass of the cellular obstacles.

Asymmetric Features

Apart from the symmetry mismatches mentioned above between penton proteins and spikes, conspicuous features that do not follow icosahedral symmetry have been observed in some of the largest DJR viruses. PBCV-1 has a unique vertex, with a pocket on the inside and a spike structure on the outside of the capsid (Fig. 8). Comparison of shape, size, and location of the spike with similar features in tailed bacteriophages suggests that it might be a cell-puncturing device. In Mimivirus, a starfish-like structure (the stargate) is present at one of the vertices. The stargate defines the first part of the mimivirus capsid to be recruited on the membrane during assembly, and the exit conduit of the genome during uncoating. Inside the icosahedral shell, the Mimivirus core has a concave depression beneath the stargate. Non-icosahedral features have also been found in one of the smallest members of the DJR lineage. Bacteriophage PRD1 also has a unique vertex, where the viral DNA enters and exits the capsid. At the unique vertex, the packaging complex replaces the regular 5-fold structure and crosses the lipid bilayer. This complex consists of a packaging ATPase (P9), a packaging efficiency factor (P6), heterodimers of proteins P20 and P22, and the genome terminal protein P8 which functions as a valve, closing the channel once the genome is inside.

Table 1 Double jelly-roll virus families for which the major capsid protein and/or capsid structures have been studied

Example virus and family name	Host	Capsid diameter	Triangulation number	Genome type and approximate size	Accession number in structure databank
Prokaryotic host - bacteria					
PRD1, <i>Tectiviridae</i>	Gram-negative bacteria	70 nm	$T = 25$	linear dsDNA, 15 kbp	PDB 1W8X
PM2, <i>Corticoviridae</i>	<i>Pseudoalteromonas</i>	60 nm	$T = 21d$	circular dsDNA, 10 kbp	PDB 2W0C
<i>Salisaeta</i> Icosahedral phage 1 (SSIP – 1), <i>Sphaerolipoviridae?</i> , Unclassified	<i>Salisaeta sp</i>	100 nm (single jelly roll?)	$T = 49$	circular dsDNA, 44 kbp	EMD 2061
Flavobacterium-infecting, lipid-containing phage (FLiP), Unclassified	<i>Flavobacterium sp.</i>	55 nm	$T = 21d$	circular ssDNA, 9 kb	EMD 3771
Prokaryotic host – archaea					
STIV, <i>Turriviridae</i>	<i>Sulfolobus solfataricus</i>	96 nm (with turrets) 73 nm (without)	$T = 31d$	circular dsDNA, 18 kbp	PDB 3J31
HHIV – 2, <i>Sphaerolipoviridae</i> ^a	<i>Haloarcula hispanica</i>	80 nm (single jelly roll)	$T = 28d$	linear dsDNA, 30 kbp	EMD 0172
Eukaryotic host					
Paramecium bursaria chlorella virus 1 (PBCV – 1), <i>Phycodnaviridae</i>	<i>Chlorella variabilis</i>	190 nm	$T = 169d$	dsDNA with covalently closed hairpin termini, 330 kbp	PDB 1M4X
<i>Phaeocystis pouchetii</i> virus 1 (PpV01) <i>Phycodnaviridae</i> or <i>Mimiviridae</i> : under debate.	<i>Phaeocystis pouchetii</i> (phytoplankton)	220 nm	$T = 219$	485 kbp	–
Cafeteria roenbergensis virus (genus Cafeteriavirus, <i>Mimiviridae</i>)	<i>Cafeteria roenbergensis</i> (zooplankton)	300 nm	$T = 499$	730 kbp	EMD 8748
<i>Acanthamoeba polyphaga</i> Mimivirus (APMV), genus Mimivirus, <i>Mimiviridae</i>	<i>Acanthamoeba polyphaga</i>	500 nm	$T = 972\text{--}1200$	linear dsDNA, 1180 kbp	EMD 10623
Sputnik, <i>Lavidaviridae</i>	Amoebae/Mimivirus (virophage)	75 nm	$T = 27$	circular dsDNA, 18 kbp	EMD 5495

Capsid Size Determination in the DJR Lineage

A large variety of capsid sizes can be built with DJR capsomers of essentially the same diameter (Fig. 7 and Table 1). To build a larger particle using building blocks (capsomers) of a similar size, viruses in the DJR lineage adopt larger triangulation numbers. That is, they build their icosahedrons with more capsomers per facet. An intriguing question is how the capsid size is determined for each particular virus, because in principle their capsomer size and shape would allow building particles of different geometries. Obviously, there is a relationship between the genome size and the internal capsid volume, since larger genomes require larger capsids to hold them. However, some of these viruses (e.g., PRD1) assemble an empty capsid into which the genome is later packaged. Therefore, at least in this case, the genome itself cannot direct the assembly of a correctly sized particle.

A possible mechanism to determine capsid size is the use of minor coat proteins acting as a “tape measure”. Similarly to adenovirus, other members of the DJR lineage have minor coat proteins on the inner and outer capsid surfaces, helping to assemble and stabilize the virion. One of these proteins, called P30, has been proposed to act as a tape measure in bacteriophage PRD1. With an extended conformation, P30 runs from the icosahedral fivefold region to the two-fold symmetry axes, following the inner surface of the icosahedron edges. This arrangement suggested that P30 could be the main player in determining particle size and, consequently, the T number. A tape measure protein has also been found in phage Bam35, a *pseudoT* = 25 virus that infects Gram-positive hosts (whereas PRD1 infects Gram-negative hosts).

Fig. 7 From the simplest to the most complex double jelly roll virus structures solved so far. The structures of the major capsid protein monomer (top row) and trimer (middle row) are shown, together the complete capsid (bottom row) of bacteriophage PM2, human adenovirus, and Faustovirus. These viruses represent the simplest and most complex examples for which both the high resolution structure of the major coat protein and at least the general capsid organization have been solved. While the PM2 major coat protein is formed by the double jelly roll motif with no more elaborations, the adenovirus and Faustovirus proteins have extensive tower domains which establish intricate interlacing in the trimer. Database identifiers and triangulation numbers are shown by each structure. The color bar indicates capsid radii, in nm. Figure reproduced from San Martín, C., van Raaij, M.J., 2018. The so far farthest reaches of the double jelly roll capsid protein fold. *Virology Journal* 15, 181.

An exception to the use of larger triangulation numbers for increasing capsid size is found in adenovirus. With the same triangulation number (*pseudo*T = 25) as the smaller lineage member PRD1, adenovirus packages more than double the genome length (35 kbp vs 15 kbp in PRD1). One way to achieve a larger capacity in adenovirus is to dispense with the internal membrane. The other is to increase the diameter of the capsomer itself. In the adenovirus hexon monomer, a small β -sheet parallel to the capsid surface is intercalated between the two orthogonal jelly rolls (Fig. 2(a) and Fig. 7), moving them apart to produce a wider pseudo hexagonal base. No tape measure element has been found in adenovirus. The principles that determine adenovirus capsid size are unknown.

Polintons and the Evolutionary Pathway of DJR Viruses

A remarkable evolutionary connection has been found between viruses in the DJR lineage and large (15–20 kbp) eukaryotic dsDNA transposons called Polintons. Polintons are so named because they encode a protein-primed DNA polymerase (to sustain self-replication, POL) and a retroviral-like integrase (INT). Many also include genes for a DNA-packaging ATPase and a maturation protease like those found in DJR lineage viruses. Exhaustive sequence analyses revealed that these transposable elements also encode genes that could translate into double or single jelly roll proteins, suggesting that at some point in time, or in certain conditions, they could form icosahedral capsids. In the light of these findings, an evolutionary model has been proposed in which

Fig. 8 Different architectures of vertex spikes in DJR viruses. Colors refer to the type of host (archaea: red; bacteria, yellow; eukaryotic, green). Database identifiers for the maps used are as follows: HHIV-2 (EMD-3110), SH1 (EMD-1498), STIV (EMD-5584); bacteriophage P23-77 (EMD-1525), PBCV-1 (EMD-1597), and HAdV-D26 (EMD-8471). The scale bar represents 100 Å.

a primordial, PRD1-like phage encoding a DJR capsid protein, a protein-primed DNA polymerase and a packaging ATPase would have invaded a proto-eukaryotic host with a bacterial endosymbiont (a mitochondrion, for example). This primordial phage would somehow have reached the nucleus, and recombined with a eukaryotic transposable DNA element carrying the integrase and maturation protease. This “polintovirus” element would have then evolved in separate ways to produce the polintons (transposable, capsid-less integrating elements), and a variety of eukaryotic “free-standing” viruses, all the way from adenovirus to mimiviruses.

Glossary

3' RNA Refers to the RNA end with a free hydroxyl 3'OH group. This end is the last incorporated by the polymerase and the first read for the synthesis of the complementary RNA strand.

5' RNA Is the RNA end with a free phosphate 5'-ppp triphosphate base. Is the first incorporated by the polymerase during RNA synthesis.

Alpha helix A common motif in the secondary structure of proteins as a consequence of the helical arrangement of the amino acids. This secondary structure is stabilized by hydrogen bonds maintained by the amino acid backbone between consecutive helical turns.

Beta sheet A common motif in the secondary structure of proteins as a consequence of the lateral packing of extended amino acid stretches (beta strands). These structures are stabilized by hydrogen bonds maintained between the backbones of the amino acids forming parallel or antiparallel strands.

Budding Process of enveloped virus assembly by which the viral proteins and RNA are packed into a membrane envelope borrowed from the cell membrane.

C terminus Refers to the carboxy end of the polypeptide chain, belonging to the last residue incorporated by the ribosome during protein synthesis.

Hydrophobic Are those compounds or amino acids that are unable to maintain interactions with water molecules, thus tend to cluster together or to interact with hydrophobic environments, like the interior of lipid bilayers.

N terminus Refers to the amino end of the polypeptide chain, belonging to the first residue incorporated by the ribosome during protein synthesis.

Phospholipids Molecules consisting of two hydrophobic fatty acids and a hydrophilic head consisting of a phosphate group. They generate lipid bilayers and are the major components of cell membranes.

Protein domain Is the protein folding unit. Each domain forms a compact three-dimensional structure that can often be independently stable.

Protein loops Protein fragments with no secondary structure and often flexibly deployed from the protein.

Prologue

Negative single stranded RNA viruses (NSRV) are a vast group of plants, animals and human pathogens that includes many relevant human pathogens with serious impact on public health at a global scale. Examples of well-known viruses belonging to this group are Influenza virus which causes yearly pandemic infections around the globe; Ebola and Lassa virus, which cause hemorrhagic fever and cause high mortality among infected patients; Respiratory syncytial virus, which is responsible of severe respiratory disease in newborns and a major concern in pediatrics; and Rabies virus, a zoonotic virus causing severe nervous system infections and that is still present in under-developed countries representing an real health risk, although the first viral vaccine against Rabies was developed by Pasteur in the 1880s. These viruses, among others, have been veritable flagships for the research on NSRV providing critical clues on viral molecular biology, mechanisms for triggering and evasion of the immune response or their viral epidemics. However, these are only the tip of an iceberg that includes hundreds of viral strains with rich diversity in the molecular mechanisms of infection at all levels including the transmission routes, the unique mechanisms of genome replication and transcription, the genome encapsidation in viral particles, the ways of counteracting the immune response and their virion structures.

In this article, we will focus on the current knowledge of the structural basis of NSRVs virions, tackling the structural components associated to different processes of the viral cycle. The aim is to give the reader insight on the mechanisms by which the different virion components, namely proteins, lipids and nucleic acids, together perform the essential processes of virus infection leading to disease. Through techniques such as nuclear magnetic resonance (NMR), X-ray crystallography and electron Cryo-microscopy (Cryo-EM), a large number of proteins and RNA structures of NSRVs have been reported. This structural information

provides, at the atomic level, a large body of knowledge illustrating how infection occurs through the molecular interplay of the different factors forming the virions. Based on this information we can more accurately understand the effect of mutations in a viral strain, explain, to a certain extent, the reasons for conservation or variability of the viral genomic sequences and understand the evolution of the viruses by gain or loss of function. In addition, the atomic structures provide the necessary information for the development of small molecules that can be used as effective treatments for viral diseases by blocking essential catalytic functions or protein interactions. In conclusion, structure determines the function, and through the structural understanding of biological processes we can reach an in-depth comprehension of life and, in this particular case, of infection.

Classification of NSRVs and Genome Organization

NSRVs are included in the Phylum *Negarnaviricota*. This classification is based on the configuration of their genomes and RNA and protein sequence similarities. Briefly, two main NSRV sub-groups are defined by their genomic segmentation. The non-segmented NSRVs that have a single RNA genomic segment (Subphylum *Haploviricotina*), and the segmented NSRVs (Subphylum *Polyploviricotina*) in which the genome is split in two to eight segments. Most of non-segmented NSRVs are included in the Order *Mononegavirales*; Important pathogens like Ebola virus (Family *Filoviridae*), Respiratory Syncytial Virus and Metapneumovirus (Family *Pneumoviridae*), Rabies (Family *Rhabdoviridae*) and Measles (Family *Paramyxoviridae*) are included in this order of viruses. The segmented RNA viruses are mainly classified in two groups, the order *Articulavirales*, including all strains of influenza (family *Orthomyxoviridae*), with genomes split into seven or eight segments, and the large order of *Bunyavirales*, including Rift Valley fever (Family *Phenuiviridae*), Crimean Congo Fever (Family *Nairoviridae*) or Lassa viruses (Family *Arenaviridae*), whose genomes are split in mainly two or three genomic fragments. An important reclassification of these viruses occurred in the recent years, thus in old bibliography this classification varies. What is important to retain is that NSRVs can be segmented or not and this has a direct impact on their biology, from the mechanisms of transcription and replication to the genome packing and structure of the virions.

General Features of NSRV Virion Structures

The common intrinsic feature of NSRVs is that their genomes are composed of RNA of negative polarity, meaning that the nucleotide sequence of the RNA is complementary to the messenger RNAs that are translated by the cellular ribosomes into proteins. In contrast, positive stranded RNA viruses can, just by delivering their positive sense RNAs into the infected cell, directly promote the synthesis of the viral proteins that will take over the cell. In other words, the positive RNA is infectious but the negative RNA is not and needs transcription to become infectious. This strategy for genetic storage challenges the NSRVs to carry all the machinery within the viral particles required to perform transcription after entering the infected cells, leading to translation of viral proteins.

NSRVs have membrane enveloped virions containing the viral genome assembled with the replicational-transcriptional machinery (Fig. 1). These assemblies are usually called nucleocapsids (NCs) or ribonucleoproteins (RNPs), the latter term being used for orthomixoviruses (e.g., Influenza virus) and bunyavirales (e.g., La Crosse virus). The virus envelope is covered by the viral glycoproteins and eventually accessory proteins. All are integral membrane proteins that cross the lipid bilayer and have a part of the protein inside the virion and a part exposed at the surface. Protein glycosylation is achieved by adding long sugar chains at specific sites by the Golgi apparatus of the cell. Glycoproteins recognize the target cell receptors and are generally the major target of neutralizing antibodies, so they aim, as far as possible, to avoid being recognized by immune system antibodies, whilst facilitating the transit through the host organisms and reach the target cells. The glycoproteins specifically recognize target cell receptors and mediate membrane fusion between the viral envelope and the target cell membrane. The part of the glycoprotein inside the virion is small and often maintains interactions with a shield of matrix protein between the lipid envelop and the nucleocapsid or RNPs. This shield underneath the lipid envelope is present in non-segmented viruses and in Influenza-like viruses but is absent in bunyavirales where the glycoproteins are in direct contact with the RNPs. These networks of interactions confer a dynamic stability to the virion that is important for its correct assembly and disassembly during the infection cycle.

The basic configuration of NCs or RNPs consists on the viral RNA genome assembled with multiple copies of the viral NP, that shield the RNA molecule, and at least one viral polymerase. Thus, the non-segmented genomes include one big NC while the segmented include several smaller RNPs into the viral particle. Importantly, non-segmented viruses include an additional viral phosphoprotein (P) in their NCs, that is essential for replication activity. NC assemblies confer stability to the RNA molecule and can determine the shape of the viral particle. For instance, the long nucleocapsids of filoviruses (e.g., Ebola), that package one ~18 Kb (~18,000 nucleotides) long RNA molecule in helicoidal nucleocapsids, confer to the virion a filament shape that can reach ~900 nm in length and 80 nm broad. Rhabdoviruses (e.g., Rabies) package their ~11–15 Kb long genomes into broad helicoidal nucleocapsids, conferring to the virion a bullet-like shape of 180 nm long and 75 nm of diameter in the basis. The rest of non-segmented NSRVs have normally a spherical shape. Paramyxoviruses (e.g., Measles) or pneumoviruses (e.g., RSV) package their genomes (RNAs between 13 and 15 Kb long) in spherical virions of ~150 nm diameter. On the other hand, all segmented NSRVs virions have a globular shape. Orthomyxoviruses (e.g., Influenza) and bunyaviruses (e.g., RVFV) package their RNPs in virions ~80–120 nm diameter. The RNA segments of Influenza comprise in total 13,5 Kb of RNA, and for the different tri-segmented bunyaviruses the total length varies between 11 and 19 Kb.

Fig. 1 Schematic drawing of a negative stranded virus taking paramyxovirus as an example. The draw shows the virus enveloped by a lipidic membrane. In the membrane are shown the viral glycoproteins responsible of cell binding and membrane fusion, they are anchored to the membrane by a transmembrane region and are in contact with the matrix proteins which form a shield of square shaped dimers of matrix proteins, the monomers are folded into beta sheets (β -S in the inset panel M). Inside the matrix we have the nucleocapsid made of the vRNA genome of negative sense completely covered with nucleoproteins (partially un-covered in the drawing for clarity) and one polymerase (L) in complex with phosphoproteins. The nucleoproteins are folded in alpha helixes (α -h in the inset panel NP) and are bilobular with a central positively charged crevice with the RNA bound. NPs are forming an helical mega complex by NP–NP contacts through flexible arms and the RNA. The polymerase, L, is linked to the NC through the tetrameric phosphoprotein (P) which binds both the L protein and the NPs (marked at b). The top inset panel shows the polymerase in complex with the tetrameric phosphoprotein. vRNA accesses the polymerase through the IN channel and exits through the OUT channel. To allow RNA synthesis the L protein has in addition an NTP entry channel and a product exit channel (PRO) from where the newly synthesized RNA comes out. In case of replication the product is a new vRNA and in case of transcription is a capped mRNA after its labeling by the capping domains (CD). When the polymerase is synthesizing RNA in the cell cytoplasm it is attached to the NC and harbors RNA inside (shown at a). It can also (e.g., in the context of the virion) be simply attached through contacts bridged by the phosphoprotein (shown at b).

Structure of the Virion Surface

Structure and Function of Virion Glycoproteins

Glycoproteins coating NSRV virions are very diverse in their structure, assembly, receptor recognition and membrane fusion mechanisms. In all cases the glycoproteins mediate the proper virion attachment to the target cell and trigger the internalization of the viral particles into the cell. The two main structural elements of the glycoproteins are the region specifically binding the cellular receptor and the region that fuses the virus and cell membranes for delivering the viral RNPs or NCs into the cell. These two regions are often in the same glycoprotein but can also exist in different glycoproteins, as in the case of paramyxoviruses, where receptor binding is mediated by the hemagglutinin-neuraminidase (HN) protein and membrane fusion by the fusion protein F. Nevertheless, the two proteins work tightly together ensuring that binding to the receptor is coupled to subsequent membrane fusion.

Target cell binding is achieved by specific interactions of certain exposed regions of the glycoproteins that have stereochemical complementarity with the cell receptor, like keys that specifically fit into a particular lock. These protein regions are called receptor binding domains and are the main target for the neutralizing antibodies, which are produced by the immune system and compete with the receptor for binding in order to block viral entry. The glycoprotein's affinity to cellular receptors is usually not very high but the accumulation of high numbers of glycoproteins in the virion surface results in the interesting phenomenon of avidity by which the glycoproteins act as a sort of "velcro", increasing the affinity of an otherwise weak interaction. The virus is thus able to through more or less specific interactions with cellular surface factors. For instance, cellular glycoproteins as DC sign (phlebovirus, Ebola) TIM1 and 4 (Ebola) Sialic acid (Influenza, Ebola) have been identified as receptors and co-receptors for NSRVs. The interaction with the right combination of specific receptors is a major determinant of cellular tropism for the virus and triggers the internalization of the virion through cellular endocytic pathways, the membrane protein recycling system of the cell. The endosomes progressively increase the proton concentration inside, this reduction of pH is detected by the glycoproteins triggering a drastic conformational change (from prefusion to post-fusion states) that allows the insertion of the so-called fusion peptides

into the endosomal membrane. The fusion peptides are short hydrophobic loops of the polypeptide chain that anchor the glycoprotein to the endosomal membrane, allowing the subsequent drawing together of the viral and endosomal membranes leading to their fusion. Upon fusion, the viral replication machinery is released into the cellular cytoplasm.

Interestingly, the three different classes of fusion proteins identified in nature, can be found among NSRV glycoproteins. Influenza virus Hemagglutinin and Ebola virus glycoproteins are class I fusion proteins. They are generated by a single polypeptide precursor that is subsequently cleaved by a cellular protease into two subunits. The subunits stay covalently linked by a disulfide bond. One is responsible for receptor recognition (HA₁ and GP₁ for influenza and Ebola respectively) and the second (HA₂ and GP₂) is responsible for membrane fusion and anchors the protein to the virion membrane by a transmembrane region. The protein cleavage, carried out by furin-like cellular proteases, is required for fusion activity. The virion is coated by these activated glycoproteins forming metastable trimers.

Bunyavirales glycoproteins are class II fusion proteins, which are heterodimers of glycoproteins Gn and Gc. They are also produced as glyco-polypeptides that, after cleavage by the cellular protease (signalase) in the endoplasmic reticulum, become heterodimers. Further processing may occur depending on the viral strain. The Gn/Gc complex associates into larger complexes driving virion budding and inducing the necessary membrane curvature. Gn is responsible for receptor recognition and Gc is a class II fusion protein. Unlike the class I fusion glycoproteins of Influenza and Ebola virus or other class II fusion proteins in nature (e.g., in positive stranded RNA viruses Flavivirus and Alphavirus), the Gn/Gc complex does not need proteolytic processing in the cell surface for fusion activation. These glycoproteins tend to form a tight lattice on the virion surface. For Hantavirus (a family of bunyavirales) has been nicely shown the tetrameric spikes (form by four heterodimers) arranged into a tight lattice stabilized by contacts between spikes.

Finally, Rhabdovirus glycoprotein G is a class III fusion protein. It is monomeric and forms trimers in the virion surface. In this case the only factor that triggers the fusion state are differences in protonation (pH) of the environment. Unlike the other classes, the pre-fusion and post-fusion states are reversible, conferring a dynamic nature to these fusion proteins.

The fusion mechanisms are determined by the structure of the glycoproteins. Class I proteins (Influenza, Ebola) have a central stem consisting of mostly alpha helices shrouded by the receptor binding domains. Lowering the pH of the activated glycoprotein triggers a drastic conformational change that extends the central stem, casts aside the receptor binding regions, and inserts hydrophobic residues at the tip into the lipid bilayer of the endosome membrane. Bunyavirus Class II fusion dimers, in contrast, have two stems (one for each monomer), bridged by a domain rich in beta sheets. The low pH triggers the stems to move closer, forcing the extension of the beta sheet domain harboring the hydrophobic loops (fusion peptides) at its tip, to penetrate the endosomal membrane. Class III proteins are more dynamic and have a central trimeric stem surrounded by domains rich in beta sheets that points towards the virion. The low pH causes a 180-degree rotation of the beta-rich domains towards the endosome membrane, joining together the fusion peptides from the tip of the three subunits and allowing their insertion in the endosomal membrane. In all cases the glycoproteins in the post-fusion state bring together the two membranes, leading to membrane fusion.

Overall, the glycoproteins are more-or-less sensitive to different markers of the virion life cycle. The need of proteolytic activation of the protein fusion prevents the virion from prematurely fusing to the cell of origin, so it can be ready to infect the next one. The interaction with specific receptors allows the internalization of the viral particle and the decrease of pH in the endosome triggers the post-fusion state. The viral glycoproteins act as sensors that control a well-programmed mechanism for virion spreading. It is remarkable that whilst there is no homology between the glycoproteins of NSRVs influenza, bunyavirus or Rhabdovirus these instead show homology with fusion machines found in other less related viruses and organisms. Thus class I fusion proteins are found in retroviruses as HIV, Bunyavirus class II fusion glycoproteins have homologs in positive stranded RNA viruses as flavivirus and Alphavirus, and even in the cell fusion protein of *C. elegans* EEF-1, while the Rhabdovirus class III fusion proteins are homologous to glycoproteins in herpesvirus (a DNA virus). These reflect the apparently independent evolution of the glycoproteins and viruses and illustrates the genetic exchange between organisms during evolution or, in other words, "the mosaic nature of viral genomes, which are a patchwork of genes having different origins (Guardado-Calvo and Rey, 2017).

Accessory Proteins in the Virion Surface

NSRVs can incorporate additional viral proteins in the virion surface. The most remarkable example is the neuraminidase of influenza virus. This protein cleaves the sialic acid (the receptor moiety recognized by the viral glycoprotein) of cellular glycoproteins. This cleavage allows the release of the virions that otherwise would be retained in the cell of origin, rendering the cleavage essential for influenza infectivity. Paramyxovirus also incorporates neuraminidase activity but in the same protein that recognizes the receptor, the hemagglutinin-neuraminidase glycoprotein. Other NSRVs lack any neuraminidase.

Influenza virus also incorporates a small membrane protein (M2) in the virion membrane. This protein forms tetrameric pores that function as a pH-sensitive proton conducting channel essential for virus infectivity. In addition, M2 interacts with the matrix protein coating the inner side of the virion membrane.

Other viruses incorporating auxiliary proteins are those from the family pneumoviridae (e.g., Metapneumovirus). The G protein and sh proteins are present in the virion surface, but are not essential for the infection. The heavily glycosylated G protein is disordered and modulates the innate and adaptive immune responses by providing a heavily glycosylated shield to the virion, thus preventing their recognition by neutralizing antibodies. As a consequence, the incomplete immunization of the host permits reinfections. The hydrophobic sh is of unknown function, has nevertheless been shown to be important for the infection in vivo.

Inside the Virion

The Matrix Proteins

Matrix proteins are essential for virion formation and stability. They generate a two-dimensional network underneath the virion envelope, connecting the different components of the virion by simultaneously interacting with membrane lipids, glycoproteins and NPs. In consequence matrix proteins are directly involved in the recruitment of all the above factors that are necessary for the budding of the RNPs or NC into virions at the cell membrane. With the exception of bunyavirales, all NSRVs have matrix proteins buttressing the viral envelope. In mononegavirales the matrix proteins are small and folded in two very similar beta-strand rich domains. These matrix protein monomers form square shaped dimers (e.g., Ebola VP40, Paramyxovirus M and Borna disease virus M proteins), which are the building blocks of a two-dimensional lattice by interdimer contacts through their square vertices. One side of the protein is very positively charged, generating an extended positively charged network that is important for binding to the negative phosphate moieties of the envelope phospholipids. Through this mechanism the matrix proteins confer a dynamic stability to the viral particle. Orthomyxoviruses have a different matrix protein (M1) which however meets the same functional needs. As reported for the infectious salmon anemia virus, M1 folds in two domains exclusively composed of alpha helices. One domain has a positively charged side facing the viral envelope whilst the other is oriented towards the virion core facing the RNPs. M1 oligomerizes to generate a very tight matrix network, much denser than in the mononegavirales. Once again, the diversity of protein structures addressing the same functional needs is a characteristic of this group of viruses, as if all possible alternatives were explored during their evolution.

The Viral Ribonucleoproteins/Nucleocapsids Assemblies

To incorporate all the replication machinery into compact small virions NSRVs have adopted the strategy of coating their RNA with NPs, small RNA binding proteins capable of self-associating into linear scaffolds that bind and cover the length of the gRNA. In all cases the inter-NP interactions generate a more-or-less pronounced helical arrangement. In addition, the RNA-NP assemblies incorporate at least one copy of the viral RNA dependent RNA polymerase, responsible for the transcription and replication of the genome. The flexibility of the inter NP interactions allows the vRNA to be compacted for packing into virions and relaxed to allow the polymerase to access and read the RNA template. The nucleocapsids or RNPs are thus functional units where all the protein factors act in an intimate and coordinated fashion to carry out replication and transcription. In addition, the interactions of the NC and RNPs with the internal tails of the matrix proteins or the glycoproteins guides the correct budding of the genomes into the virions.

The mononegavirales NCs are linear and, in addition to the gRNA, the Polymerase (L protein) and the nucleoproteins, incorporate phosphoproteins (P) that, by interacting with the polymerase and NPs, play a key role in coordinating the NC function. Conversely, each genomic segment of segmented NSRVs is assembled in circular RNPs. The circularization was thought to be caused by the RNA base-pairing of the genome ends, since all genomic segments have a strong sequence complementarity. Instead, the reported structures on Influenza polymerase and La Crosse bunyavirus L protein in complex with vRNA showed that the circularization is mediated by the interaction of the polymerase with the RNA ends in two different binding sites, specific to each end. In addition to this circularization, the RNPs also maintain a helical arrangement ranging from the highly coiled double helix of Influenza to circular flexible helices of bunyaviridae.

The Nucleoproteins

NSRV NPs are broadly diverse, as is the case for other proteins of the virion. The NP function is to stabilize and linearize the gRNA preventing, to an extent, the formation of secondary structures. The NPs are generally kidney-shaped globular proteins folded in alpha helices that are able to coat the RNA by defining two important surfaces in their structure, the RNA binding groove and the oligomerization interface. The positively charged groove, formed by the two lobes of the kidney-like structure, accommodates the negatively charged RNA. Multimerization is often achieved by N and C terminal extensions of the polypeptide chain acting as arms to grab the neighbor interacting proteins in a head to tail fashion. Upon multimerization, the NP grooves generate a long positively charged channel that accommodates the long gRNA molecules. The interaction of NP and vRNA is sufficiently non-specific to permit the encapsidation of the entire gRNAs independently of their sequence. However, the NPs specifically cover the gRNA and not viral mRNA or any other RNA in the cell. The mechanisms of specific encapsidation are related to the capacity of RNA-binding inhibition of the NPs that can be mediated by interactions with the P protein (mononegavirales) or self-inhibition of the monomeric NP (bunyavirales). This inhibition is eliminated by specific RNA sequences and/or the polymerase during the synthesis of the newly synthesized gRNAs. Further experimental evidence is required to clarify these mechanisms.

The arrangement of NPs on the gRNA is different for segmented and non-segmented NSRVs. The structure of measles or Ebola virus nucleocapsids shows the NPs closely interacting with each other side to side. They form a broad helical assemblies with the RNA binding sites facing the exterior. The flexible extensions on both sides of the NP interact with the neighboring NPs conferring further stability to the assembly. The gRNA is tightly bound to the NPs but remains accessible to the polymerase from the exterior of the helix. Contacts between NPs of adjacent helical turns compact and rigidify the assembly. The sizes of these helices are variable; Ebola nucleocapsid helices have a diameter of ~ 295 Å and ~ 19 NP per turn, compared to the ~ 190 Å diameter and ~ 12 NP per turn helices of measles. In both cases 6 nucleotides of the viral RNA are accommodated per NP. Conversely, the

segmented NSRV NPs tend to form narrower helical assemblies with the RNA binding groove facing the interior of the helix. This is the case for members of the families *Peryorthobunyaviridae* (e.g., Bunyamvera or La Crosse viruses) and *Phenuiviridae* (e.g., Rift Valley fever virus). The RNA, inside the helical structure, would be inaccessible to the polymerase, which relies on flexible NP arms connecting the proteins to allow the eventual flipping of the NPs, transiently exposing the RNA to the exterior. However, more rigid RNP structures are found, as in the case of Hantaviridae family members (e.g., Hantaan or Andes virus) where the NPs weave a net of interactions building a very closed and rigid helical assembly with the RNA inaccessible in the interior. How RNA is synthesized by the polymerase in these structures is still an open question.

Not surprisingly, we can find interesting variations of the NP structure. Arenavirus (members of the family *Arenaviridae*, order *bunyavirales*) have larger NPs that incorporate an additional domain consisting of an exonuclease able to cleave RNA. The function of this endonuclease is related to the suppression of the interferon response and, although its importance in viral replication is limited, mutant viruses lacking this activity are not able to infect animals, providing another example of the importance of viral interference with the host immune response for successful infection. Another peculiar NP belongs to the Influenza virus (and other viruses included in the family *Orthomyxoviridae*). These NPs coat circular gRNAs that coil further in a flexible double helix assembly of variable diameter ($\sim 150\text{--}200\text{ \AA}$). NPs cover the RNA head to tail and constitute a bunyavirus-like circular assembly with the polymerase holding both RNA ends. In addition, influenza NPs interact in an antiparallel fashion generating the supercoil resulting in a double helix formation. The inter-strand NP–NP contacts are very flexible allowing the displacement of one NP–RNA stream over the other. This very sophisticated mechanism allows the polymerase to read the whole genome in a compact RNP assembly, while keeping both RNA ends attached (see relevant web pages for explanatory videos).

The Polymerase

sNSRV polymerases are large multifunctional proteins able to transcribe and replicate the viral RNA. They are monomeric (single polypeptide chains), referred to as L proteins, with the notable exception of the heterotrimeric Influenza polymerase (made of three different proteins). Their size is generally around 2250 amino acid residues but viruses belonging to certain families (e.g., *Nairoviridae*) have polymerases of around 4500 amino acids. The polymerase perform RNA dependent RNA synthesis that, for replication, is coordinated with the assembly of new RNPs by coupling the RNA synthesis to the incorporation of NPs and, in segmented viruses, at least one polymerase on the nascent strand. Transcription is achieved by incorporating the molecular labels rendering the viral mRNAs recognizable by the cellular translational machinery. These modifications are the polyadenylation, capping and methylation of the RNA. Thus these polymerases adopt two modes of RNA synthesis, one incorporating NPs in the nascent RNA (replication) and the other labeling the uncoated RNA to resemble a cellular mRNA (transcription).

The polymerases of NSRV have all the basic canonical RdRpol fold with palm, fingers and thumb subdomains. In addition, similarly to polymerases of double stranded RNA viruses (e.g., reovirus), they incorporate N-terminal and C-terminal extensions forming an enclosed chamber connected to the exterior by four tunnels. Inside the chamber, the emerging product and template RNA strands are separated at an early stage of RNA synthesis (Fig. 1). Template entry and exit tunnels are close to each other facilitating reading the genome with minimal RNP disruption, while the product exit tunnel guides the nascent transcript or replicate towards the RNA transcription processing machinery, which is flexibly linked to the core. This flexibility is important for adopting different functional conformational states that determine the transcription or replication mode of the polymerase.

Beside these common features, segmented and non-segmented NSRV have substantial differences in their mechanisms of transcription and this is reflected by different structures of their transcription processing machinery. Non-segmented viruses perform transcription by capping and methylating the RNA with a polyribonucleotidyltransferase (PRNTase) and a methyltransferase domain included in their polymerases at the C terminus. These two domains respectively transfer the GTP moiety to the nascent RNA and methylate this GTP in the N7 position. The PRNTase is included in the core of the polymerase and the methyltransferase is flexibly linked at the exit of the product exit channel, allowing the RNA to be capped upon the exit from the polymerase core.

Segmented NSRVs polymerases perform transcription by cap-snatching. They “snatch” 5′ short capped fragments from the cellular mRNAs using domains with distinct cap-binding and endonuclease activities. These domains are at the N and C terminus of the RdRpol core respectively. Interestingly, despite the lack of amino acid sequence conservation, all these polymerases have a similar overall architecture. Another striking feature of segmented NSRVs polymerases is their interactions with the vRNA. Two RNA binding sites specific for the 5′ and 3′ vRNA ends hold the RNA molecule and cause its circularization. 5′ binding allosterically regulates the active site of the RdRpol and 3′ binding tightly holds the RNA during the pre-initiation and the elongation of the RNA synthesis, maintaining the circular structure of their RNPs. This elaborate mechanism allows vRNA to regulate the polymerase activity and keeps it always bound to the RNP.

Phosphoproteins

Perhaps because of the absence of the polymerase–RNA interactions seen in segmented viruses, non-segmented NSRVs include an extra protein in their nucleocapsids: the phosphoprotein. This protein is mostly disordered, can be phosphorylated and forms tetramers. A central domain made of alpha helices mediates tetramerization as well as the interaction with the L protein, resulting in the formation of a functional complex with L protein with a 4:1 ratio. The N terminus interacts with the viral NP preventing its nonspecific binding to cellular RNAs and thus rendering it available for the nucleocapsid assembly. The C terminus interacts with the N terminal tail of NP engaged in the NP–NP multimerization interface in the nucleocapsid, assuring attachment to the

nucleocapsid. However, the N and C termini have also been shown to interact with the L protein inducing certain conformational changes regulating its activity. Thus, P proteins have several ways of interacting with the L and the NP proteins and this network of interactions is a major regulatory factor of transcription and replication. The P protein thus facilitates the access of the L protein to the gRNA template in the NP, allows the incorporation of RNA-free NPs to the nascent nucleocapsids during gRNA synthesis and regulates L protein activity.

Concluding Remarks

As we have seen, NSRV biology is complex because of the diversity in the molecular mechanisms they have developed. Despite maintaining some basic principles, NSRVs have adopted at all levels (e.g., transcription, replication, membrane fusion) an original set of solutions to face the biological challenges for infection. In comparison to prokaryotic or eukaryotic organisms, which share highly similar basic molecular processes, NSRVs can be regarded as veritable bio-reservoirs of alternative molecular pathways. A single chapter does not allow an in-depth description of all the biology known for them. Furthermore, the study of poorly known NSRV viral families will reveal new variations on the mechanisms described here. Thus, studying NSRVs will not only be crucial for facing possible future pandemic challenges but will also expand our very basic molecular understanding of life.

Structure of Retrovirus Particles (*Retroviridae*)

David K Stammers and Jingshan Ren, University of Oxford, Oxford, United Kingdom

© 2021 Elsevier Ltd. All rights reserved.

The presence of virions is characteristic of the basic requirement for the propagation of viruses to be sustained (Vogt, 1997). Knowledge of the structure of virions or their components represents an important means of understanding the functioning of such systems. Enveloped RNA viruses are made up of a range of constituent parts that must carry out five main functions: (1) an enzyme for copying the viral RNA in the newly infected cell (in the case of –ve strand RNA viruses and retroviruses), (2) formation of the genome in complex with proteins, (3) packaging of this RNA-protein complex inside a capsid shell, (4) an envelope added to the capsid in the form of membrane lipids and (5) addition to the envelope of proteins that contain the molecular recognition determinants for binding to a host cellular target and promoting membrane fusion (Vogt, 1997). The assembly of the virion structure together with the encapsidation of the genomic RNA form a ‘late stage’ in the virus life cycle.

Retroviruses are RNA viruses, which are enveloped, and have been shown to target a wide range of species. A retrovirus is so-called because of the flow of information from the genetic material is in a backward (retro) direction i.e., from RNA → DNA → RNA → protein rather than the more usual route, namely DNA → RNA → protein. A key property of retroviruses is the integration of a DNA copy of the viral genomic RNA into the host genome (the provirus), using the virally encoded integrase. The activity of the provirus thus makes an infection persistent, potentially requiring lifelong therapy in the case of a virus causing human disease such that caused by Human immunodeficiency virus (HIV). In contrast, for many other viruses the infection is only transient or may flair up intermittently in which case drug treatment, if available, is required only for a limited period.

Retroviruses are thought to have evolved from Long Terminal Repeat (LTR)-retrotransposons (Dodonova *et al.*, 2019), which are transposable elements that can form a significant proportion of an organism’s DNA. In the case of the human genome it amounts to ~8% of the total DNA. Retrotransposons do not have an extracellular phase of their life cycle and thus are less easily able to spread to other cells. The evolution of retrotransposons into retroviruses appears to be via the acquisition of a lipid coat together with an *env* gene, the product of which recognizes a cellular receptor on a target tissue of particular organisms infected and promotes fusion of lipid membranes from the virus and host, hence propagation of the virus (Dodonova *et al.*, 2019).

The first retroviruses to be identified were Rous sarcoma virus (RSV) and mouse mammary tumor virus (MMV), both tumor inducing viruses found in mice. It was also later shown that a long known disease giving rise to anemia in horses was also caused by a retrovirus, in this case equine infectious anemia virus (EIAV) (Vogt, 1997).

Retroviruses are important human pathogens. Human T-cell lymphotropic virus I (HTLV1), which can cause a T-cell leukemia, is an early example. A more recent threat to human health is the global pandemic of Acquired Immuno-Deficiency Syndrome (AIDS) which was caused by a retrovirus, HIV. In this syndrome the infection by HIV results, if untreated, in an eventual catastrophic depletion of CD4⁺ lymphocytes thereby making individuals susceptible both to opportunistic infections as well as to various cancers.

A further factor in making HIV-1 infection so persistent is the rapid turnover of the virus with a cycle time of 1–2 days. Such rapid replication together with the error prone viral reverse transcriptase lacking any editing or corrective functions results in the generation of many mutant forms of the viral genomes (Coffin, 1995). As a result drug treatment will potentially rapidly select resistant virus from the array of quasi-species present, an effect that can be countered to a greater extent by the use of multi-drug cocktails. New drugs acting on novel target sites are required to maintain the ability to suppress HIV infections. Only a limited number of anti-HIV drugs target the virion structural proteins (as opposed to the vast majority of anti-HIV drugs that inhibit the pol enzymes) including the fusion inhibitor enfuvirtide and the co-receptor antagonist Maraviroc. Currently there are experimental compounds that target the HIV-1 capsid protein but as yet none have been approved for clinical use (Purdy *et al.*, 2018).

HIV-1 has thus been intensively studied in order to provide a better understanding of the properties of the virus. Such research has yielded much structural data which have been invaluable in assisting in the development of new drugs against a range of viral targets particularly the pol enzymes. A continued further long term aim is to utilize structural data to aid in the design of vaccines, which to date have proved extremely difficult to develop against HIV due to the ability of the virus to evade the immune system. A useful vaccine is still seen as an important goal in order to prevent further spread and eventual elimination of HIV and AIDS (Ward and Wilson, 2017).

On account of this focus there has been a very significant number of studies of the structural aspects of HIV-1 which have included the whole virus in both immature and mature forms, as well as protein components. Use of X-ray crystallography or solution NMR of individual proteins and cryo-EM of macromolecular assemblies of virus components have been combined to greatly improve the understanding of the relation of structure to function. HIV-1 is by far the most studied retrovirus we thus use this virus as the main example in describing retroviral virion structure. Due to space limitations it is not possible to refer to all the research papers in this field, rather the many excellent review articles which describe both the overall retrovirus virion structure as well as components should be referred to for more detailed information (Conte and Matthews, 1998; Briggs and Krausslich, 2011; Sundquist and Krausslich, 2012; Mattei *et al.*, 2016b; Perilla and Gronenborn, 2016; Pornillos and Ganser-Pornillos, 2019; Zhang *et al.*, 2015; Chen, 2019; Wilen *et al.*, 2012; Ward and Wilson, 2017).

Gag Proteins and Retroviral Virion Structure

The assembly of the immature retrovirus, following viral gene expression which in turn leads to virion maturation, occurs towards the end of the phase of retrovirus infection. These events follow the earlier phases of cell entry, reverse transcription and DNA integration into the host genome.

The assembly of retroviruses is directed by the viral protein, Gag, the Group-specific antigen protein which forms the main structural component. The expression of Gag (p55 for HIV) is sufficient for the production of non-infectious virus-like particles (VLPs), (Briggs and Krausslich, 2011). Gag is a polypeptide that has several protein domains interspersed by flexible linker regions. Three of the Gag domains show conservation across retroviruses (Fig. 1). Firstly the matrix protein (MA) which directs Gag to the plasma membrane and also assists in the viral glycoprotein Env being incorporated into the assembling virions (Murakami, 2008). Secondly the capsid protein (CA) which is involved in forming oligomers of Gag leading to capsid formation and thirdly the nucleocapsid protein (NC) which binds to nucleic acids including the genomic RNA allowing it to be packaged into the newly formed virus. The assembly of these components leads eventually to the mature HIV virion (Fig. 2). Details of the structural changes going from the immature to mature HIV virion are shown in Fig. 3.

The exact composition of Gag varies amongst different retrovirus genomes as seen in comparison of the gag genes of HIV-1, RSV, Mason-Pfizer monkey virus (*m*-PMV) and murine leukemia virus (MLV). In some cases there are short linker peptides as is the case for HIV, where SP1 and SP2 as well as p6 are released by the viral protease (Mattei *et al.*, 2018) (Fig. 1). For HIV-1 the pol gene

encodes enzymes required for replication of the virus (including reverse transcriptase and integrase) and is translated as a Gag-pol fusion protein following a (–1) ribosomal frameshift event. The latter occurs with a frequency of 1 in 20, hence providing the means for producing the correct ratio of Gag to pol proteins as required for virion production and genomic RNA transcription into DNA which is subsequently integrated into the host DNA. During the virus maturation phase these individual proteins of the gag-pol polyprotein are released by the action of the HIV protease. The protease also further processes the reverse transcriptase to form the active p66/p51 heterodimer, retaining one RNase H domain in the p66 subunit and additionally yielding an isolated p15 RNaseH domain which is apparently non-functional.

There are two types of Gag proteins as seen in the pathway followed for morphogenesis of new virus. For lentiviruses, type C viruses and most other retroviruses (Mammalian & Avian) the Gag proteins are targeted to the plasma membrane where immature particle formation followed by budding occurs. For Type D and Type B viruses (M-PMV and MMTV, respectively) the Gag protein precursors first assemble into a core particle which is subsequently transported to the plasma membrane for release (Conte and Matthews, 1998; Briggs and Krausslich, 2011; Perilla and Gronenborn, 2016).

Gag proteins form the principal components of the HIV-1 virion, accounting for 50% of the mass, whilst viral membrane lipids make up approximately 30% of the virion mass (Sundquist and Krausslich, 2012). Other viral and cellular proteins amount to ~20%, whilst the two copies of the genomic RNA together with other small RNAs account for ~2.5% of virion mass. Virally encoded proteins such as reverse transcriptase, integrase, protease and the nucleocapsid protein are also present in the virion, as is t-RNA-lys3 which is required as a primer for the reverse transcription of the genomic RNA into DNA. We will focus on the structures of the Gag proteins as these form the main constituents of the virion and are largely responsible for the assembly of new virus.

Structures of Individual Gag Domains

It has not proved possible to determine the structure of the full length Gag protein due to the presence of flexibility in the interdomain linker regions which results in a heterogeneous protein conformation precluding structure determination. Instead structures of the larger individual Gag domains have been determined to high resolution using crystallography or NMR.

Matrix Protein (MA)

The Matrix protein (MA), also referred to as p17 in HIV, forms the outer shell of the virion just beneath the lipid membrane (Figs. 2 and 3(a)). In HIV, MA is co-translationally modified by the addition of a myristoyl group on the N-terminus. Such a modification is essential for trafficking of the Gag protein to the plasma membrane which is the site of virion release. Also required are a group of positively charged residues that form a basic patch interacting with the acidic head groups of various phospholipids located in the inner leaflet of the plasma membrane including phosphatidylinositol 4,5-bisphosphate (PIP2) (Lingappa *et al.*, 2014).

In none of the numerous cryo-EM studies of the structure of HIV-1 virions, whether from the mature or immature virus, did the MA domain give any indications of forming an organized structure relative to the capsid domain (Mattei *et al.*, 2016b; Pornillos and Ganser-Pornillos, 2019). As a result of this lack of order, detailed structural information of MAs from different retroviruses has relied upon the study of isolated domains.

Retroviral MAs can vary significantly in length from 100 residues for M-PMV to 150 residues for the protein from RSV. The 3-D structures of several recombinant retrovirus MAs have been determined by use of NMR or X-ray crystallography. These structures include examples from HIV-1, simian immunodeficiency virus (SIV), human T-cell leukemia virus type II (HTLVII), bovine leukemia virus (BLV), M-PMV & MLV (Conte and Matthews, 1998). MAs from different viruses share little sequence identity, yet the protein folds all consist of mainly α -helices. In some cases similarities in structure have been noted by visual inspection (Conte and Matthews, 1998). However, in another example it did not prove possible to overlap HIV-1 MA with M-PMV MA, hence they contain distinctive folds (Fig. 4(a) and (b)). Analysis of the packing in the crystal structures of SIV MA showed the presence of a trimer that is related by a non-crystallographic three fold axis (Rao *et al.*, 1995). Later work on HIV-1 MA revealed the same trimeric assembly in several crystal forms, in one case this was located on a crystallographic three-fold axis (Hill *et al.*, 1996). In the MA trimer the conserved basic residues of lysine and arginine present in the N-terminal region form a surface which in conjunction with the myristol group could orientate the trimer towards the membrane (Fig. 4(c)) (Rao *et al.*, 1995; Hill *et al.*, 1996; Conte and Matthews, 1998). It is also interesting to note that MA trimerisation is known to be necessary for the incorporation of the trimers of gp120/gp41 into the HIV virion surface (Murakami, 2008; Tedbury *et al.*, 2016).

Capsid Protein (CA)

The capsid protein (CA) forms the basic building block of immature and mature retroviruses (Perilla and Gronenborn, 2016). It is positioned inside the MA layer of the virion forming the outer region of the core (Fig. 3). CA is a flexible molecule and can readily undergo the conformational changes necessary for the transition between the immature and mature states. A further important property of CA is its ability to form different states of oligomerisation including hexamers and pentamers which are necessary for the formation of the capsid (Perilla and Gronenborn, 2016). CA is reported to have essentially identical three-dimensional structures for most retroviruses (Perilla and Gronenborn, 2016) of which the protein from HIV-1 is the most studied example.

CA consists of about 230 amino acids and is organized into two lobes or domains called CA-NTD (N-terminal domain) and CA-CTD (C-terminal domain) which are both largely α -helical. CA-NTD consists of ~ 150 amino acids and has seven helices. CA-CTD contains four α -helices and additionally a 3_{10} helix (Fig. 5). A region around residues 150–170 is referred to as the major homology region (MHR) and is highly conserved amongst retroviruses. Deletion of the MHR inhibits virus assembly.

One of the main properties of CA is its flexibility, as demonstrated by the linker between NTD and CTD allowing different relative domain orientations which relate to the assembly state of the virion (Fig. 3). CA can oligomerise into a number of different aggregation states, which have particular functional roles. Thus hexamerisation of CA yields the basic unit for capsid formation but

(b) M-P M virus matrix protein (PDB:1BAT) (c) SIV matrix protein showing trimer (PDB:1ECW). The conserved positively charged residues that are thought to interact with phospholipids in the membrane are marked in gray.

Fig. 5 HIV capsid protein structure CA, (a) monomer showing N-terminal domain (NTD) in blue and C-terminal domain (CTD) in orange (PDB: 3NTE). The major homology region (MHR) consisting of residues 153–172 is colored pink. (b) Hexamer native form (PDB:4XFX).

in order to enclose space, pentamers must also be incorporated, a total of 12 pentamers being required in this case. Early studies introduced disulfide bridges into CA to stabilize the hexamer or pentamer forms (Pomillos *et al.*, 2011). More recently full length unmutated CA has been crystallized as a hexamer leading to the visualization of the native contacts (Gres *et al.*, 2015).

Nucleocapsid Protein (NC)

NC is of variable length depending on the particular retrovirus and contains one or two zinc fingers as well as positively charged regions. NC is a multi-functional protein, its primary role is to act as a chaperone for nucleic acids, remodeling them in order to give the most thermodynamically stable conformations (Levin *et al.*, 2010). The protein is responsible for recruiting two copies of the viral RNA genome into the newly forming Gag complex and hence is required for virion assembly. In the case of HIV the RNA genome amounts to ~10,000 bases per copy. Further functions for NC include the placement of primers such as the annealing of a tRNA molecule (tRNA^{lys3} in the case of HIV-1) onto the primer binding site on the viral RNA, required for the initiation of the reverse transcriptase reaction.

The main structural feature of the HIV NC protein is the presence of two zinc finger domains (also called zinc knuckles) each containing the metal-ion binding motif CX₂CX₄HX₄C. The two domains are interconnected by a flexible basic linker region which is largely disordered in solution. The NMR structure with a bound RNA fragment consisting of the stem-loop s12 of the psi-RNA packaging signal has been determined (Amarasinghe *et al.*, 2000) (Fig. 6).

Linker Peptides

In HIV-1, three additional short peptides are released from Gag following protease processing (SP1, SP2 and p6). SP1 has been shown to have a role in CA assembly whilst the function of SP2 is unclear (Mattei *et al.*, 2016b). The short linker peptide following SP2 and thus positioned at the C-terminus of HIV-1 Gag is p6, which has been shown to be a site for docking various cellular as well as viral binding partners and appears important for the production of infectious viruses. Most of its known functions are suggested to occur under hydrophobic conditions near the cytoplasmic membrane and some formation of helical regions at the N- and C-termini have been demonstrated in micelles but it is otherwise largely unstructured (Solbak *et al.*, 2013).

Other components incorporated into the virion include viral accessory as well as various cellular proteins, small RNA molecules, and specific lipids. The relevance of the presence of these various factors is generally not fully understood (Sundquist and Krausslich, 2012).

Assembly of the Immature Retroviral Virion Leading to Maturation and Release of Virus

The mechanisms underlying the assembly of immature retrovirus virions followed by the transition to the mature form have been intensively studied. Many excellent reviews have been published on the subject particularly focussing on HIV and the extensive primary scientific literature is fully documented therein (Briggs and Krausslich, 2011; Sundquist and Krausslich, 2012; Mattei *et al.*, 2016a,b).

Fig. 6 NMR solution structure of HIV-1 Nucleocapsid protein (p7). The zinc ions of the 2 p7 zinc fingers are shown in purple. The bound RNA is the stem loop SL2 of the psi RNA packaging signal (PDB: 1F6U).

Many structure determination methodologies have been used in studying retrovirus virion proteins. Thus crystallography and NMR have been used for high resolution studies of isolated Gag domains as described above, such structures are useful for fitting into lower resolution maps of the whole virion derived from cryo-electron microscopy (cryo-EM) imaging. Cryo-EM is pivotal for structural studies of both assemblies of CA and the whole virus but has not proved straight forward as for both immature and mature HIV-1 particles since the virions are pleomorphic. Such variability in the immature capsid structure is demonstrated by various spherical forms that contain defects (de Marco *et al.*, 2010). For the mature virion the capsid adopts various morphologies (Fig. 3(a)) (Mattei *et al.*, 2016b). This variability is in contrast to the requirements of single particle cryo-EM where identical particles are picked for averaging. However the development of more powerful microscopes together with improvements in detector technology, data acquisition and processing have contributed to significant progress being made. Cryo electron tomography has been used whereby a number of 2D images collected at differing tilt angles are combined to give a medium resolution image. A further pivotal development is sub tomogram averaging where the resolution of the structure determination can be significantly improved to the sub nanometer level (Mattei *et al.*, 2016b).

The initial assembly of the immature virus is directed by Gag which yields a spherical shell that MA anchors to the viral membrane. The co-translational modification consisting of an N-terminal myristoyl chain in the case of HIV MA, as described previously, is placed in the inner part of the membrane bilayer and the positively charged region binds to the head group of PIP2 (Fig. 3(a)). Membrane budding occurs after the assembly of a curved Gag lattice (Pornillos and Ganser-Pornillos, 2019).

The next step is the auto-activation of the protease, cleaving Gag at the recognition sites (Fig. 1) which in turn leads to the Gag lattice disassembling and the formation of a ribonucleoprotein particle from the newly released NC in complex with the genomic RNA in a form ready for reverse transcription (Pornillos and Ganser-Pornillos, 2019). The cone like capsid is formed (Fig. 3(b)) with the dense NC-RNA particle at one end. The cone of HIV is thought to utilize fullerene type geometry where largely hexameric units require the incorporation of exactly twelve pentamers in order to close the capsid shell (Sundquist and Krausslich, 2012). Other retroviruses have differing core morphologies from HIV. Thus the M-PMV core has a cylindrical shape whilst MLV is more spherical. In each case twelve pentamers are present in the capsid but their relative positions are thought to vary (Mattei *et al.*, 2016b; Zhang *et al.*, 2015).

It can be seen that the immature hexamer has extensive contacts made by α -helices from CTD of CA and SP1 close to the six-fold axis (Fig. 3(c)) (Pornillos and Ganser-Pornillos, 2019; Schur *et al.*, 2015; Mattei *et al.*, 2016b). On transition to the mature form of HIV a significant reorganization of CA occurs such that NTD helices form the main contacts donating 3 helices per CA giving a ring of 18 helices (Fig. 3(d)) (Mattei *et al.*, 2016a). The mature pentamer structure is shown in Fig. 3(e), the contacts formed in hexameric and pentameric oligomers have been shown to be quasi equivalent (Mattei *et al.*, 2016b).

Accompanying the transition from immature to mature HIV virions two potentially significant structural changes that might be determinants for the structural maturation were observed. These changes are (1) a β -hairpin formation at the N-terminus of the CA protein and (2) destabilization of a 6-helix bundle made up from the C-terminus of CA and the adjoining SP1. (Mattei *et al.*, 2016b; Pornillos and Ganser-Pornillos, 2019). It was not clear as to how particular proteolytic cleavages contribute to the alterations in the protein structure. The structures of a series of mutants at the sites of cleavage were determined and further analysis indicated different cleavages can lead to destabilization of the 6-helix bundle which therefore acts as the switch of HIV virions to the infectious form (Mattei *et al.*, 2018).

CA is a potential site for the development of ‘maturation inhibitors’ as anti-HIV drugs. Compounds that bind to the six-helix bundle and prevent it from unwinding have been identified (Purdy *et al.*, 2018; Pornillos and Ganser-Pornillos, 2019).

Structure of ENV

The *env* gene product or “spike protein” is a glycoprotein located on the virion surface that plays an essential role in viral transmission by firstly promoting attachment to cellular surfaces through the recognition of specific receptors. Subsequent entry into the cell is promoted by fusion of the cellular and viral membranes, leading to the release of the RNA genome into the host, thereby giving rise to a further cycle of virus infection.

For HIV-1 the initially synthesized polypeptide, gp160, is organized into a homotrimer. gp160 consists of a number of motifs and domains spanning intracellular and extracellular regions that have different functions (Fig. 7). There are 5 variable loops and 5 conserved loops in the extracellular region which is then followed by the fusion peptide, 2 heptad repeats, the trans membrane region and the cytoplasmic tail.

A further post translational modification occurs when gp160 is subjected to proteolytic cleavage by a cellular enzyme, furin. The resulting fragments, gp120 and gp41 form a trimer of heterodimers that remain associated in a non-covalent manner. gp120 forms the receptor binding site and for this role is positioned on the surface of the virus. gp41, which is responsible for membrane fusion, is more closely associated with the lipid bilayer, possessing a trans membrane domain in addition to the ectodomain (Fig. 7). The attachment of gp120 to target cells is by binding to one domain of the CD4 receptor located on immune cells (e.g., T helper cells, monocytes and macrophages). Additional interactions generally are also made to a co-receptor which is either of two chemokine receptors, CCR5 or CXCR4 (Fig. 8). gp120 is heavily glycosylated with >80 sites being modified (Fig. 7), thus forming a “glycan shield” to help fend off the immune system (Ward and Wilson, 2017).

The envelope protein of HIV-1 is a major viral target for the host immune system. HIV hides from the immune system in a number of ways including the presence of flexible loops or “variable” loops in gp120 that can easily mutate. An important objective in the structural studies of gp160 was the understanding of the basis for the action of “broadly neutralizing antibodies” (which can target gp160 from many different clades) in order to be able to design new immunogens for a novel vaccine.

The availability of detailed three-dimensional structural information on gp160 was considered to be of crucial importance in the understanding of underlying mechanisms which would in turn contribute to vaccine design. Considerable efforts by many

Fig. 7 HIV-1 Env The full-length HIV-1 Env, gp160. Segments of gp120 and gp41 include: C1–C5, conserved regions 1–5; V1–V5, variable regions 1–5; F, fusion peptide; HR1, heptad repeat 1; C–C loop, the immunodominant loop with a conserved disulfide; HR2, heptad repeat 2; MPER, membrane-proximal external region; TM, transmembrane anchor; CT, cytoplasmic tail; tree-like symbols, glycans. Fig. 8 Overview of HIV entry. To deliver the viral payload into cells, HIV Env, comprised of gp120 and gp41 subunits (1), first attaches to the host cell, binding CD4 (2). This binding causes conformational changes in Env, allowing coreceptor binding, which is mediated in part by the V3 loop of Env (3). This step initiates the membrane fusion process as the fusion peptide of gp41 inserts into the target membrane, followed by six-helix bundle formation and complete membrane fusion (4). Reproduced from Wilen, C.B., Tilton, J.C., Doms, R.W., 2012. HIV: Cell binding and entry. Cold Spring Harbor Perspectives in Medicine 2, with permission.

groups over several years has now yielded very significant progress. In this context the major advances in higher resolution cryo-EM structure determination made over the last decade have greatly contributed to the success of such research efforts.

The first structure determined of a fragment of gp160 was part of the ectodomain of gp41 complexed with a solubilising peptide (Weissenhorn *et al.*, 1997) which showed an all helical structure consisting of an extended, triple-stranded α -helical coiled coil with the amino terminus at its tip. A carboxy-terminal α -helix packs in the reverse direction against the outside of the coiled coil, as seen in other viruses therefore suggesting a common mechanism for initiating fusion (Figs. 8 and 9(a)).

Crystallization of the cleaved gp120/gp41 has proved problematic as the heterodimer is unstable when located outside of the virion. Focussing initially on the gp120 core domain some of the flexible surface loops (V1-V5) were truncated and the heterogeneity of the glycosylation sites reduced in order to give a more homogeneous protein that was more likely to crystallize (Ward and Wilson, 2017). Further efforts included co-crystallization with various receptor fragments as well as with antibody Fabs. A huge effort to survey many conditions lead eventually to the crystallization and structure determination of the core gp120 in

Fig. 9 Structures of HIV gp41 and gp120 domains.(a) Structure of gp41 ecto domain in post fusion state showing helix bundle (PDB:1ENV) (b) gp120 core domain (green) in complex with CD4 soluble domain (orange) and Fab fragment (domains blue and red) (PDB:1GC1).

Fig. 10 The structure of a cleaved HIV-1 envelope glycoprotein in complex with a neutralizing Fab PGT122. Chains of the gp41 trimer are shown in red, green and blue, and the corresponding chains in gp120 in salmon, pale green and slate respectively. The glycans on the glycoprotein are drawn as sticks. The Fabs are shown in orange (heavy chains) and cyan (light chains). Arrows indicate the gp120 and Fab interface (PDB : 4NCO).

deglycosylated form, with variable loops truncated and in complex with the soluble domain of its receptor (sCD4) and the Fab of a CD4i neutralizing antibody (Kwong *et al.*, 1998). The structure of the deglycosylated core gp120 is a prolate ellipsoid organized into a novel fold consisting of two major domains containing 25 β -strands and 5 α -helices and 6 disulfide bridges (Fig. 9(b)) (Kwong *et al.*, 1998).

A further major step in obtaining the crystal structure of the trimer of the homodimeric gp120/gp41 complex was the introduction of a disulfide bridge between gp120 and gp41 to hold the subunits together. In conjunction with a single point mutation in the HR1 region of gp41 that improves stable trimer formation, the construct (SOSIP) (Sanders *et al.*, 2013) in a particular stable strain (BG505) together with a suitable Fab fragment and some deglycosylation gave protein that yielded well ordered crystals leading to structure determination at 4.7 Å (Julien *et al.*, 2013) and also a cryo-EM structure at 5.8 Å in which full glycosylation was retained (Lyumkis *et al.*, 2013; Ward and Wilson, 2017). The new structures revealed the protein including the gp41 in some detail together with its interactions with gp120 and the spatial arrangement of V1/V2 and V3 loops (Fig. 10). Of particular interest for vaccine design was the interactions of the Fab of a broadly neutralizing antibody. A long extension from the antibody projects through the coating of sugar chains and into a conserved region of gp160.

Conclusions

Much new information has been derived for the structure of retrovirus virions particularly for HIV. Combining structural results from cryo-EM, crystallography and NMR has shown atomic resolution detail of the Gag domains, Matrix, Capsid and Nucleocapsid, the principle components of the HIV virion. Studies of the immature and mature forms of HIV have revealed the mechanism of the transition between the two states. A future challenge is the utilization of these structural data for developing novel therapies for HIV. Whilst prototype compounds are available for inhibiting the maturation phase there are still many other potential sites on the Gag domains and other virion proteins that can potentially be exploited for drug design (Tedbury and Freed, 2015).

For ENV, extensive protein engineering has allowed crystallization of ENV domains leading to detailed structures in conjunction with cryo-EM studies which should be of value in immunogen design for more effective vaccines against HIV.

Glossary

4-Helix bundle A family of protein folds consisting of 4 α -helices oriented with the long axes of the helices roughly parallel to each other. The direction of the helices with respect to each other (parallel versus antiparallel) and the order in which the polypeptide connects them determines the specific type, or fold of 4-helix bundle.

Capsid The protein coat that encloses the viral genome.

Cryoelectron microscopy A method for visualizing biological structures by suspending unstained objects in a thin sheet of non-crystalline (vitreous) ice. Computer assisted averaging is utilized to reconstruct 3-dimensional images of the object. In favorable cases, the technique can reach high enough resolution to allow de novo modeling of protein and nucleic acid structure.

Envelope A lipid membrane, usually derived from the cellular membrane, with inserted viral glycoproteins. Envelopes are present in many viruses as an external layer

wrapped around the nucleocapsid, though some viruses may instead utilize an internal lipid envelope. The envelope is usually a lipid bilayer, but in hyperthermophiles, membranes are frequently a monolayer of cyclic lipids, with head groups on both faces of the membrane.

Helical symmetry Symmetry defined by the combination of rotational and translational displacement about a single helix axis.

Icosahedral symmetry Symmetry of a regular icosahedron, with 12 axes of 5-fold symmetry, 20 axes of 3-fold symmetry, and 30 axes with 2-fold symmetry.

Nucleocapsid Viral capsid containing the viral nucleic acid genome.

Virion A complete, infectious virus particle.

X-ray diffraction The diffraction of x-rays by oriented molecular assemblies, usually in crystals but sometimes in fibers or “sols”, used to determine the atomic structure of the object.

Introduction

The proteins that form the shells, or capsids, that encase viral nucleic acid are involved in a variety of functions, including viral assembly, cellular egress, extracellular genome protection, host recognition, entry and disassembly. Due to the need for genetic economy, these capsids are constructed of smaller protein subunits, or building blocks, that assemble through a well-defined set of interactions that are repeated over and over again to construct these beautiful, complex containers. Whenever a repeated set of interactions are used to assemble a larger structure, whether a viral capsid or some other object, the result is always symmetric and this symmetry can be either open or closed. In the case of closed symmetry, the subunit interactions will result in an assembly with a defined number of subunits arranged about a single point (point group symmetry). In contrast, open symmetry includes a translational component that instead results in an extended helical assembly.

Interestingly, nature exploits each of these principles to package viral nucleic acid, and thus most viral nucleocapsids are either closed spherical shells with icosahedral symmetry or long, filamentous tubes with helical symmetry. Among the helical viruses, some are rigid rod-shaped virions while others are flexible filamentous assemblies, and the packaged genome can be either RNA or DNA. In addition, for some helical viruses, their helical nucleocapsid assemblies are enclosed within a lipid membrane envelope. A potential advantage of the nucleoprotein helix is its ability, in principle, to package a genome of any size. However, unlike icosahedral viruses, helical viruses are recalcitrant to crystallization. Thus, high resolution structural studies of intact helical virions have historically relied on X-ray fiber diffraction and, increasingly, on electron microscopy.

Rod-Shaped Helical Plant Viruses

Helical viruses are found in each of the 3 domains of life, Eukarya, Bacteria and Archaea. Among the Eukarya, filamentous non-enveloped positive strand RNA viruses are particularly common in plants, both rigid (*virgaviridae*), and flexible (*potyviridae*,

Fig. 1 Tobacco Mosaic Virus (TMV, PDB ID 2TMV) (A) A short section of the TMV single-start, right handed helical assembly is shown. Subunits are colored in alternating shades of orange and pale-orange, and the right-handed or clockwise twist is indicated by the black arrow at the bottom of the assembly. Subunits at the top of the assembly are not shown in order to reveal the helical path of the encapsidated RNA, with the non-hydrogen atoms shown as spheres (C: beige, N: blue, O: red, P: orange). (B) Two TMV subunits stacked one on top of the other from successive strands of TMV, equivalent to an orange/orange subunit interaction in panel A. Each subunit is depicted in rainbow colors with the N-terminal residues in blue, the C-terminal residues in red, and intervening residues a gradient over the blue, cyan, green, yellow, orange and red gradient. The RNA is bound at the subunit interface towards the interior of the capsid. (C) The TMV subunit is a decorated, right-handed up and down 4-helix bundle. The 4 α -helices forming the 4-helix bundle are numbered and shown in light blue, cyan, green and yellow/orange, respectively. The 1st α -helix in light blue is at the front left side, running from bottom to top. When the polypeptide reaches the top of the 1st α -helix, it then makes a "right turn" into the 2nd α -helix (cyan), which runs in the opposite direction. Thus, the "right-handed" 4-helix bundle designation. The 2nd α -helix then connects via a long loop into the 3rd α -helix (green, back right), running bottom to top, and then into the 4th α -helix (yellow/orange) running top to bottom.

alphaflexiviridae, *betaflexiviridae*, *closteroviridae*). A prominent example is tobacco mosaic virus, or TMV, a member of the *virgaviridae*. Historically, TMV has been at the forefront of structural studies of helical viruses, and the subject of X-ray fiber diffraction studies as early as 1941. Nearly 50 years later, following a host of methodological developments and low to medium resolution structures, the structure of TMV was finally determined at 2.9 Å resolution (PDB ID 2TMV).

The earlier, lower resolution studies revealed a TMV nucleocapsid approximately 300 nm in length and 18 nm in diameter, with a hollow core roughly 4 nm in diameter running along the length of the virion. Overall, the nucleocapsid is composed of approximately 2130 identical coat protein subunits arranged in a right-handed helical assembly. A single RNA strand is nestled within a groove that follows the viral helix at a radius of 4 nm, with each protein subunit bound to three nucleotides of RNA (Fig. 1). Helical structures are characterized by their pitch (P), which is the distance along the helix axis corresponding to one full turn of helix. The pitch is equal to the number of subunits per turn of helix (u) multiplied by the relative translation or displacement of each subunit along the helical axis (p). Specifically, $P = u \times p$. For the TMV nucleocapsid, there are 16.33 subunits per turn of helix (49 in 3 turns), with each subunit displaced by 0.14 nm along the helical axis, giving a pitch of 2.3 nm (Fig. 1).

The 154 residue (17.5 kDa) TMV subunit is a right handed, antiparallel 4-helix bundle. As one follows the first helix up the fold, there is a "right turn" into the second helix (Fig. 1(C) and Table 1). In the literature, these 4 helices are designated as the LS, RS, RR and LR helices, respectively. Within the viral capsid, the long axis of the 4-helix bundle is roughly perpendicular to the long axis of the TMV capsid (Fig. 1), such that the extended loop connecting helices 3 and 4 (LR/RR) projects into the interior of the capsid. In contrast, the exterior end of the bundle is decorated by a small mixed β -sheet and 2 small α -helices, with the N- and C-termini exposed on the exterior of the capsid. There are extensive subunit interactions, both laterally to neighboring subunits within the same helical turn, and to subunits in the preceding and subsequent helical turns as well.

The RNA follows a helical path at a radius of 4 nm, running along a groove between successive helical turns of the coat protein. Thus, each 3 base segment is sandwiched between two subunits. The 1st and 3rd bases are in an *anti* conformation, with the second base in the less common *syn* conformation. The bases pack against hydrophobic side chains "underneath" helix 4 (LR) of the "upper" subunit, and the *syn* base and one of the *anti* bases stack together in a cavity between 2 inter-subunit salt bridges. For the most part, the interactions are not base specific, but there is a preference for a guanine at position 1. The charge on the phosphate groups is offset in part by Arg residues in the coat protein, as well as a Ca^{2+} ion interdigitated between 2 successive phosphate moieties and Asp116.

Table 1 High resolution structures of helical viruses

<i>Viral Family</i>	<i>Viruses</i>	<i>Genome</i>	<i>Domain</i>	<i>Rigid/Flexible</i>	<i>Twist</i>	<i>Capped</i>	<i>Enveloped</i>	<i>Subunit</i>
<i>Virgaviridae</i>	TMV TMGMCGMMV RMV ORSV	+ RNA	Eukarya (Plants)	Rigid Rod	Right-Handed, Single-Start Helical Assembly	No	No	Decorated, Right- handed 4-helix Bundle
<i>Alphaflexiviridae</i>	PepMV BaMV	+ RNA	Eukarya (Plants)	Flexible Filament	Left-Handed, Single-Start Helical Assembly	No	No	Multi-helix Bundle, With N- and C-Terminal Arms
<i>Filoviridae</i>	Ebola Virus	– RNA	Eukarya (Primates)	Flexible Filament	Left-Handed, Single Start	Yes	Yes	2-domain Multi- helix Bundles
<i>Inoviridae</i>	Fd Ike and Pf1	Single-stranded DNA	Bacteria	Semi-flexible Filament	Right-Handed, 5-Start and 6-Start Helical Assemblies	Yes	No	Single Helix
<i>Rudiviridae</i>	SIRV2	Linear Double- stranded DNA (A-form)	Archaea	Rigid Rod	Right-Handed, Single-Start Assembly	Yes	No	Homo-dimer, Decorated, Left-handed 4-helix Bundle
<i>Lipothrixviridae</i>	AFV1 SFV1		Archaea	Flexible Filament	Right-Handed Single-Start Assembly	Yes	Yes	Hetero-dimer, Decorated, Left-handed 4-helix Bundle
<i>Claviviridae</i>	APBV1	Circular Double- stranded DNA	Archaea	Rigid Rod	Left-Handed, 5-Start Assembly	Yes	No	Helix-Turn-Helix
<i>Bicaudaviridae</i>	ATSV	Circular Double- stranded DNA	Archaea	Lemon-shaped Capsid/Rigid Tail	Left Handed Multi-Start	Yes	No	Decorated, Right-handed 4-helix Bundle

The Structures of 5 additional tobamoviruses (TMGMV, CGMMV, RMV, ORSV, HLSV) have also been determined by X-ray fiber diffraction. These viruses share the same helical symmetry (16.33 subunits per turn of helix), and their respective coat proteins show sequence identity to TMV ranging from 36% to 72%. Thus, it is not surprising that they show the same overall fold. Notably, each of these structures show conservation of the Ca^{2+} mediated Asp116/phosphate interaction. Outside of these tobamoviruses, high resolution structures for other rod-shaped plant viruses are lacking. They generally exhibit helical symmetry, though the helical parameters do differ. It is expected that they will utilize subunits based on a core 4-helix bundle, but sequence differences and differences in the size of the coat proteins make it clear that there is still much to be learned.

Flexible, Filamentous Plant Viruses

While TMV and other virgaviridae are stiff, rod-shaped helical assemblies, the capsids of many plant viruses are flexible, filamentous assemblies. These include the *alphaflexiviridae*, *betaflexiviridae*, *potyviridae* and *closteroviridae*. These flexible nucleocapsids also show helical symmetry, though the helical parameters differ from the tobamoviruses. For example, Potato virus X (PVX) has 8.9 subunits per turn and a pitch of 34.5 Å. Similarly, the coat proteins show high helical content, and it was expected for some time the N- and C-termini were on the outer surface of the nucleocapsids, and that their structures would be built around a core 4-helix bundle. One difference, however, is the incorporation of additional proteins at the 5'-end of the RNA. The potyvirus protein VPg is covalently linked to the 5' end of the viral RNA and is therefore present in the virion. And in the *closteroviridae*, both a major and a minor capsid protein are utilized. The minor capsid protein coats a short segment of the genome (less than 5%), at the 5' end of the RNA, giving these viruses a "rattlesnake" like appearance.

While the earliest studies of helical virus structure relied on X-ray fiber diffraction, more recently electron cryo-microscopy (cryo-EM) has seen enormous advances in instrumentation and software that allow helical virus reconstruction by single particle analysis (SPA) or iterative helical reconstruction (IHR). These techniques have enabled structural studies of helical viruses, including flexible filamentous viruses, and are now the predominant method used for high-resolution structural studies. IHR has been employed to determine two higher resolution structures for members of the *alphaflexiviridae*, Bamboo Mosaic Virus (BaMV) and Pepino Mosaic Virus (PepMV), at resolutions of 5.6 and 3.9 Å respectively. In each case the inner and outer diameter of the capsid, the number of subunits per turn and the pitch are nearly identical to PVX (above), but the high-resolution data surprisingly revealed left-handed, rather than right-handed helical assemblies (Fig. 2 and Table 1). In addition, while the individual coat protein subunits did indeed reveal high helical content, their structures are not antiparallel, up and down 4-helix bundles like those seen for TMV. Instead, the subunit shows a large N-terminal helical bundle with uncommon 3D topology, and a small C-terminal helical lobe (Fig. 2). Importantly, the structures also reveal extended N- and C-terminal arms on the exterior and

Fig. 2 Pepino Mosaic Virus (PepMV, PDB ID 5FN1) (A) A short section, ~ 4 -turns, of the PepMV single-start, left-handed helical nucleocapsid. Each subunit is colored identically as a rainbow gradient with the N-terminus in blue and the C-terminus in red. The left-handed or counter-clockwise twist is indicated by the black arrow at the bottom of the assembly. The N-terminal extensions (dark blue) on the outside of the virus reach laterally to interact with the preceding subunit. The C-terminal extensions (red) on the interior surface of the capsid protrude from the top of the structure, where they interact axially with the next helical turn of the assembly (not shown). (B) An enlarged view of two adjacent capsid proteins. Each subunit again colored with a rainbow gradient. The left subunit (i) depicted as a ribbon, the preceding subunit on the right ($i-1$) as a rendered surface. The N-terminal arm of subunit i extends laterally to interact with a hydrophobic cleft on subunit $i-1$. (C) A single capsid protein subunit, a 2-lobed multi-helix bundle. The orientation is rotated $\sim 40^\circ$ about the vertical axis to show the RNA accommodated between the major (N-terminal) and minor (C-terminal, yellow and red helices) lobes.

interior of the nucleocapsid, respectively. The cleft between the two lobes of the core structure is utilized to accommodate 5 bases per subunit of the + sense RNA genome, which mirrors the helical symmetry of the capsid.

A key question is how does the capsid form a stable helical assembly while at the same time allowing for flexibility. In this regard, the structures show reduced lateral and vertical contacts between the helical bundles, but at the same time the extended N- and C-terminal arms make substantial interactions with neighboring subunits. Specifically, the N-terminal arm makes hydrophobic interactions with the preceding subunit ($n-1$), providing the main lateral interactions between subunits. In contrast the C-terminal arm builds structure along the interior of the capsid, first interacting with 3 subunits in the turn above ($i+7$, $i+8$, $i+9$), before pointing toward the center of the virion where the extreme C-terminal residues contact subunit $i-7$ in the turn below, to build the axial interactions that support helix formation. The flexible linkers present in the coat protein between the helical core and the N- and C-terminal extensions then allow relative movements between the coat proteins, explaining the flexible, yet stable nature of this helical virion. Surprisingly, it was recognized that the structure of the PepMV coat protein showed similarity to the nucleoprotein in the *phleboviridae*, suggesting horizontal gene transfer between these evolutionarily distant groups of eukaryotic RNA viruses.

Fig. 3 Bacteriophage fd (PDB ID 2COW) and Pf1 (PDBID 1QL2). (A) A short section of the fd, right-handed (black arrow) 5-start helical assembly is shown. The successive helicoid components are numbered and colored in green, yellow, orange, red and blue, respectively. Filamentous bacteriophage f1 and M13 show similar architectures. (B) A short section of the Pf1 capsid, illustrating its right handed (black arrow) 6-start helical architecture with successive helicoids colored in green, orange, cyan, yellow, red and blue. (C) An enlarged view of the base of the Pf1 capsid rendered to show secondary structural elements and the orientation of the subunits with the capsid. Each subunit is a single α -helix of ~ 50 amino acid residues. (D) An enlarged view of a single Pf1 subunit, its N-terminus is at the top (blue), and the C-terminus at the bottom in red. Within the capsid, the N-terminus is exposed on the outside surface of the nucleocapsid, while basic residues at the C-terminus are on the interior where they presumably neutralize the negative charge on the packaged RNA.

Filamentous Bacteriophage

X-ray fiber diffraction, solid state NMR and low-resolution electron microscopy have also been used to derive models for filamentous bacteriophage. These viruses package circular, single stranded DNA genomes within a semi-flexible nucleocapsid 6 nm in diameter and 800–2000 nm in length. Like the filamentous plant viruses, they also utilize minor structural proteins to cap the ends of the virion, with 3–5 copies of p3 and p6 at one end, and p7 and p9 at the other (Table 1). The major capsid protein is small, only about 50 amino acids (6 kDa). Solid state NMR and X-ray fiber diffraction each suggest it forms a simple, slightly curved alpha-helix (Fig. 3). The subunits form an overlapping, interdigitated helical array, utilizing hydrophobic interactions between apolar regions in the central portion of the helix. The negatively charged N-terminal region is on the outer surface and the C-terminal region is at the inner surface, where positively charged (basic) residues help neutralize the negative charge on the DNA. While the DNA has not been visualized at high resolution, it runs through the center of the helical array, and apparently does not adopt the helical symmetry of the capsid. The helical capsid thus acts as a protective sheath around the circular, single stranded DNA genome.

Two different, but related symmetry classes of filamentous bacteriophage have been identified. Phage fd, along with f1 and M13, are specific for bacteria carrying F-pili, and are thus known as the Ff or F-specific filamentous phage group, and belong to class I. The Pf1 and Pf3 strains belong to class II. The repeating unit for fd (Class I) consists of 10 subunits arranged in two interdigitated rings of five subunits each. Subunits within a ring do not contact each other, instead they interact with subunits in the second ring. The two rings are related to each other by a translation of 1.6 nm along the viral axis, and a rotation of 36° . Alternatively, one can begin with a single subunit and consider a set of repeating lateral interactions as one moves from subunit to subunit. When a single such subset is examined, it is seen that they form an open helicoid structure. In the case of fd, 5 such helicoid structures are used to complete the intact virion. Thus, rather than a single helical array as seen for the tobamoviruses, fd is a “5-start” helical assembly (Fig. 3). Similarly, the repeating subunit for Pf1 (Class II) is described as 27 subunits in 5 turns of helix with 5.4 subunits per helical turn, but can also be visualized as a 6-start helix (Fig. 3). While not discussed here, bacteriophage tail sheaths have also been described as 6-start helical assemblies. Ready examples of multistart helices outside the arena of protein quaternary structure include the right-handed threads on glass bottles and plastic beverage containers.

Hemorrhagic Filoviridae

While helical viruses are common in plants, only one family of filamentous animal viruses is known, the *filoviridae* (Table 1). Examples are Ebola virus and the related Marburg virus, which cause hemorrhagic fever with high fatality rates in humans and non-human primates. Ebola is an enveloped virus with a linear, negative sense, single stranded RNA genome of approximately 19,000 bases, that encodes 7 proteins, a nucleoprotein (NP), along with a glycoprotein (GP), a polymerase (L) and several

Fig. 4 Ebola Virus (EBV) Nucleocapsid (PDB ID 5Z9W). (A) A short section, ~ 2 -turns, of the EBV single-start, left handed helical nucleocapsid assembly is shown. Subunits are colored in a gradient of colors, and the left-handed or counter clockwise twist is indicated by the black arrow at the bottom of the assembly. The outer lipid envelope is not shown. The DNA, again rendered as spheres, is colored as in Fig. 1. (B) An enlarged view of the yellow subunit at the bottom of panel A. The EBV subunit is composed of two domains (yellow and brown), and each is a large α -helical bundle (see text). The DNA is bound between the two domains, towards the outside edge of the nucleocapsid.

“minor” structural proteins (VP24, VP30, VP35, VP40). The nucleoprotein condenses with the RNA to form a helical nucleocapsid, which forms the core of the virion. The outer viral envelope is assembled as the nucleocapsid buds through the host cell membrane into which the glycoprotein “spikes” have been inserted. VP40 and VP24 are “matrix” proteins found in the space between the envelope and the nucleocapsid, VP30 is a minor nucleoprotein, while VP35 (a chaperone to keep NP in an RNA free state) and the polymerase are present at the 3′ end of the viral RNA.

The structure of the Ebola virus NP/RNA nucleocapsid has been determined using cryo-EM single particle analysis. It assembles as a left-handed, single start helix with a pitch of 73.56 Å and 24.44 subunits per turn (Fig. 4). It has inner and outer diameters of 175 and 295 Å, respectively, and an overall length of 950 μm to accommodate a single copy of the full RNA genome.

The Ebola virus nucleoprotein, composed of 739 amino acids, is significantly larger than the capsid proteins in the helical viruses described above; its structure was first determined in the RNA free state by X-ray crystallography. It is a 2-domain protein comprised of N- and C-terminal lobes, plus an N-terminal arm and C-terminal tail. The fold of the N-terminal lobe is not easily described in detail, but is a bundle of 12 α -helices with a few minor β -strands. The C-terminal lobe, also a helical bundle, is comprised of 6 α -helices and a critical β -finger ($\beta 3/\beta 4$). The cryo-EM structure shows clear density for the RNA, which is firmly secured within a positively charged ellipsoidal cleft between the N- and C-terminal lobes. Binding of the RNA results in conformational changes in the NP, giving rise to the RNA bound “closed” conformation. The conformational change is not just a simple hinge motion between the 2 domains, but includes rearrangement of the secondary structural elements within the C-terminal domain, including substantial rotations of the α -helices and a 90° rotation of the β -finger. The RNA follows an undulating path along the nucleoprotein strand with 6 nucleotides per subunit. These nucleotides are present in a “3-bases-inward, 3-bases-outward” configuration, in which the first 3 bases point towards the exterior of the nucleocapsid, and the next three towards the interior (Fig. 4). Though they are not considered as helical viruses, this is similar to the nucleoprotein interactions seen for measles virus and parainfluenza virus.

Lateral interactions between subunits include hydrophobic interactions between the parallel $\alpha 17$ and $\alpha 18$ helices, giving rise to a “zipper” like arrangement, as well as an extensive role for the N-terminal arm on the inside of the nucleocapsid (Fig. 4). In contrast, the inter-strand interface is primarily electrostatic, which may explain why the nucleoprotein-RNA complex can easily uncoil, yet remain stable in solution.

Viruses of the Archaea, *Rudoviridae* and *Lipothirixviridae*

Helical viruses are common in the Archaeal, or 3rd domain of life, especially among thermophiles (Table 1). Thus, many of the structurally characterized archaeal viruses replicate in high temperature ($> 80^\circ\text{C}$), acidic ($\text{pH} < 4$) environments, and the virion morphologies and dynamics should be considered in the context of these unusual environments. One of the best characterized viral families in the Archaea are the *Rudoviridae*, where the structure of *Sulfolobus islandicus* Rod-shaped Virus 2 (SIRV2) has been determined using cryo-EM iterative helical reconstruction.

SIRV2 is a non-enveloped, rod-shaped virus with a linear, double stranded DNA genome. The nucleoprotein complex forms a single start, right handed helical assembly with a pitch of 42 Å and 14.67 subunits per turn (Fig. 5). In contrast to tobacco mosaic

Fig. 5 *Sulfolobus islandicus* Rod Shaped Virus 2 (SIRV2, PDB ID 3J9X) (A) A short section, ~ 2 -turns, of the SIRV2 single-start, right-handed helical nucleocapsid. The subunits are colored in a gradient of colors from orange to red, and the right-handed or clockwise twist is indicated by the black arrow at the bottom of the assembly. The A-form, double stranded DNA is rendered as red ribbons. The blue subunits at the top nicely illustrate how thoroughly the DNA is encased by the protein subunits. (B) An enlarged view of a major capsid protein homodimer. Each subunit is colored with a rainbow gradient, blue at the N-terminus, red at the C-terminus. The core 4-helix bundles are on the right side of the DNA, on the exterior of the capsid. The long, kinked N-terminal α -helices (blue, light blue, cyan) arc around the DNA to dehydrate and encase it. The A-form DNA is shown as balls and sticks, and colored as in Fig. 1. (C) A single subunit of the capsid protein colored as in panel B. The 1st α -helix of the 4-helix bundle is on the front right side. It runs up the page, and at the top of the α -helix, makes a left-hand turn into the 2nd α -helix, and is thus a left-handed 4-helix bundle. The polypeptide chain then runs into α -helices 3 and 4, and each α -helix runs antiparallel to both the preceding and following α -helices.

virus, which utilizes a right handed 4-helix bundle, the major capsid protein in SIRV2 adopts a left handed 4-helix bundle. In addition, helix 1 shows a long, kinked, N-terminal helical extension, which can be described as a helix-kink-helix motif, with a curved appearance (Fig. 5). This extension is disordered in the monomeric form of the protein, becoming ordered only when incorporated into the virion. Otherwise, this left-handed 4-helix bundle core is highly compact with short loops connecting each helix.

Within the virion, the capsid protein binds dsDNA as a set of repeating homodimers. The long axis of the 4-helix bundle is parallel to the capsid surface, with the N-terminal helix-kink-helix motif projecting inward, where it wraps around and completely encircles the dsDNA, such that the DNA is bound within a solvent inaccessible surface. Subunit interactions within the dimer are primarily hydrophobic, as are the lateral interactions between dimeric subunits. In contrast, the inter-strand interactions are largely polar. So too are the interactions with the DNA, which are mediated by conserved, positively charged (basic) side chains. Remarkably, the DNA is bound in the A-form, rather than B-form DNA typically seen in biological structures. The transition to A-form DNA is thought to stabilize the DNA genome in the acidic extracellular environment. This is likely a common mechanism for protecting DNA in harsh environments, as A-form DNA is also seen in bacterial spores.

Enveloped filamentous viruses, the *Lipothrixviridae*, are also present in the Archaea. Currently, high-resolution structural information exists for two of them, *Acidianus* filamentous Virus 1 (AFV1) and *Sulfolobus* Filamentous Virus 1 (SFV1). Their nucleocapsids show distinct similarities to SIRV2, although in contrast to SIRV2, they employ a heterodimer of paralogous proteins. AFV1 shows a variable pitch ranging from 39 to 47 Å centered on 43 Å with 9.3 heterodimers per turn, and SFV1 exhibits a 47 Å pitch with 17.14 units per turn. The major capsid proteins again adopt the right handed, antiparallel 4-helix bundle fold with a curved N-terminal helical extension. The SFV1 structure is further elaborated by a C-terminal extension, encompassing a 2-stranded antiparallel β -finger that packs against helices 3 and 4 on the outside of the nucleoprotein complex, followed by an extended random coil and two short α -helices that are collectively involved in subunit interactions with an adjacent super-helical turn. While the lateral interactions between subunits are strong, tight contacts between helical turns are lacking, potentially allowing the virion to bend. Again, the DNA is fully encased within the heterodimer as dehydrated A-form DNA, protecting it from acid catalyzed hydrolysis in the acidic hot spring environment.

Overall, however, the main feature distinguishing the *lipothrixviridae* from the *rudiviridae* is the presence of the outer lipid envelope. The AFV1 envelope is composed of cyclic glycerol dialkyl glycerol tetraether (GDGT) lipids, primarily GDGT-0, while the SFV1 envelope is dominated by archaeol, a diether lipid. Thus, both viruses specifically recruit minor host lipids, each building a membrane different from that of their host and from each other. In this context, the high-resolution helical reconstruction of AFV1 revealed an additional surprise; the envelope is half the thickness of the host membrane. In the viral envelope, molecular dynamics simulations indicated that the individual tetraether GDGT-0 lipids are likely folded back on themselves into a horseshoe-shaped configuration. Cyclic tetraether lipids have previously been observed to adopt this configuration at air water interfaces, however this represents the first indication of a biological membrane composed of this thinner monolayer of “horseshoe-shaped” lipids. Critically, the tetraether GDGT-0 lipids lack cyclopentane rings present in GDGT-4, allowing the flexibility needed to adopt this unique configuration and explaining the preferential recruitment of GDGT-0 into the viral envelope. Similarly, SFV1 shows an external lipid envelope thinner than expected. While the thickness of the envelope is consistent with an archaeol (C_{20}) monolayer thought to include a third capsid protein (VP3), it was concluded that the archaeol: VP3 viral envelope could not be reliably modeled with the information at hand. Interestingly, during budding the fusellovirus SSV1 also incorporates a GDGT-0 envelope

Fig. 6 *Aeropyrum pernix* Bacilliform Virus 1 (APBV1, PDB ID 5OXE) (A) A short section of the APBV1 capsid, illustrating its left-handed (black arrow) 5-start helical architecture with successive helicoids colored in red, blue, orange, yellow and green. The envelope is not depicted. (B) An enlarged view of the APBV1 subunit with its helix, reverse-turn, helix motif. The N-terminus in blue and the C-terminus in red. Within the capsid, the reverse-turn is exposed on the outside surface of the nucleocapsid, while basic residues at the N- and C-terminus are on the interior, where they presumably neutralize the negative charge on the packaged B-form DNA. While not resolved at high resolution, the DNA appears to adopt the 5-start symmetry of the capsid, though there must be symmetry mismatches in places.

with reduced thickness suggesting a related membrane structure, at least during this stage of the viral life-cycle. Thus, lipid monolayers of single-leaflet dimensions may play a critical role in the life cycles of thermophilic viruses.

Claviviridae

Aeropyrum pernix Bacilliform Virus 1 (APBV1) is the only representative of the *Claviviridae* family (Table 1). Although its nonenveloped rod-shaped morphology is reminiscent of the *Rudiviridae*, the 3 Å iterative helical reconstruction and *de novo* modeling of the VP1 coat protein distinguish it as an unrelated virus family. Subunits are organized as a left-handed 5-start helical assembly with 21.75 subunits per turn and a pitch of 133.7 Å (Fig. 6). The glycosylated major capsid protein uses a helix-turn-helix motif with a type-1 β -hairpin to form the turn. Overall the virion is highly compact with extensive helix-helix packing and an abundance of hydrophobic contacts. Relative to the abundance of 4-helix bundles described for other helical viruses, the packing of one helix-turn-helix motif upon its neighbor gives a similar structure, although this gives neither a right, nor left-handed up and down 4-helix bundle topology. The axis of each VP1 helix lies along the capsid surface with the helix curvature dictating the overall curvature of the virion. Minor structural proteins assemble to cap each end of the virion, with 5 terminal fibers used for cell adhesion extending from one end.

The circular double stranded DNA genome was not visualized at similarly high resolution, but it is known that it is nicked and therefore in a relaxed, as opposed to supercoiled form. Low resolution density that follows the symmetry of the 5-start helical coat protein is seen on the interior of the nucleocapsid. This symmetry gives rise to positively charged tracks formed by Lys9 and Arg79 with spacings that mirror the distance between phosphate groups in B-form DNA. In addition the genome appears fully hydrated, which is also consistent with B-form DNA. While the *rudiviridae* and *lipothrixviridae* inhabit thermo-acidic environments, APBV1 was isolated from a near neutral pH hot spring, potentially explaining the presence of B-form DNA in this archaeal virus.

Spindle-Shaped Viruses: *Bicaudaviridae* and *Fuselloviridae*

While clearly not classical helical viruses, the archaeal spindle-shaped viruses (Table 1) do show interesting parallels to helical viruses. These lemon-shaped viruses are divided into 2 families, the *bicaudaviridae* (large tailed spindles, 50–100 kbp ds DNA

Fig. 7 *Acidianus* Tailed Spindle Virus (ATSV, PDB ID 5EQW) (A) Large tailed spindle-shaped viruses like ATSV generally exit the cell as lemon- or spindle shaped particles that mature into smaller lemon-shaped particles with extended tail structures at one or both ends. Here, ATSV is modeled as a left-handed multi-start helix. (B) The ATSV subunit is depicted in rainbow colors, with the N-terminus in blue and the C-terminus in red. It is a decorated, right-handed 4-helix bundle, with a small capping β -sheet and extended hydrophobic loop on top, and a 5th helix at the C-terminal end. Within the capsid, the long axis of the 4-helix bundle runs $\sim$ parallel to the long axis of the capsid. Lateral interactions within a helicoid strand are extensive, but the inter-strand interactions are more modest, potentially allowing the rope-like strands to “slip” past each other as it transitions from the metastable lemon-shaped capsid to the tubular structure.

genomes) and the fuselloviridae (smaller tailless spindles, 15–20 kbp ds DNA genomes). For the Bicaudaviridae, as the virus matures, the lemon-shaped capsid transitions into an elongated cylindrical form at one or both ends of the capsid, giving the appearance of tail growth. Similarly, the fuselloviridae are seen to transform into empty cylinders in response to chemical perturbation. While we lack structural information on the fuselloviridae, coat protein structures have been determined for two members of the bicaudaviridae: *Acidianus* Two-tailed Virus and *Acidianus* Tailed Spindle Virus (ATSV). Like tobacco mosaic virus, the central fold consists of a classic right-handed antiparallel 4-helix bundle (Fig. 7). In addition, the helix is capped end on by a small, mixed β -sheet, although the β -cap is at the opposite end of the helical bundle relative to the cap on TMV, and a short 5th helix is found at the C-terminus.

The ATSV capsid protein crystalizes as a left-handed four-start helical assembly with 10 subunits per turn of a single helical strand, suggesting a similar structure for the virus tail (Fig. 7). The long axis of the helical bundle lies parallel to the long axis of the helical assembly, not radially as in tobacco mosaic virus. Combined with radially symmetric striations on the surface of the spindle-shaped capsid in cryo-EM micrographs, this led to a proposed architecture in which a multi-start helix of varying width forms the lemon-shaped capsid that then extends into the tail, with the dsDNA genome packaged asymmetrically within the lemon-shaped capsid. However, it was instead modeled as a 6-start helical assembly in order to fit the diameter of the observed tail to the model. The true helical parameters remain unknown.

Subunit interactions in the crystal reveal extensive intra-strand contacts, with minimal inter-strand contacts. The combination of strong intra-strand and weak inter-strand forces could allow the capsid coils to slip past one another, smoothly altering the capsid diameter as it transitions to the lower energy cylindrical state. It is likely that the dynamic nature of multi-start helical assemblies will be a unifying feature of spindle-shaped virions, and that the transition from the metastable spindle-shape to the lower energy tailed helical structures are the driving force for genome delivery into the host cell.

Overall, lipid envelopes are so far found in 11 of the 18 archaeal virus families, many of them from high temperature acidic environments. Archaeal lipids composed of fused diethers or tetraether components show extremely low proton permeability indicating that one function in the virion could be the protection of the packaged viral genome from the acidic environment. Intriguingly, a number of these viruses selectively acquire a subset of host lipids. The fuselloviridae and lipothrixviridae envelopes are composed primarily of GDGT-0 (SSV1 and AFV1) or archaeol (SFV1), which have much higher flexibility than the GDGT-4 (GDGT with 4 cyclopentane groups) that predominates in the membranes of their hosts. These flexible lipids are likely required to facilitate the high membrane curvature of fuselloviridae and lipothrixviridae capsids. Increased environmental stability is another rationale for selected lipid acquisition. SH1 enriches its membrane with PGP-Me which is known to increase membrane stability in the high salt environments inhabited by this virus.

While the unique properties of these envelopes solve one problem, they raise new ones. Specifically, SSV1 has been shown to bud from the host cell in a manner reminiscent of eukaryotic viruses, and it seems likely that of the many enveloped archaeal viruses, at least some of them will fuse with host cell membranes to deliver their genomes. How do these viruses bud from or fuse with membranes composed of membrane spanning cyclic tetraether lipids that are frequently found in thermophilic archaea? The presence of such membrane spanning lipids would seem to prohibit the separation of the membrane into the individual leaflets characteristic of the hemi-fusion intermediate proposed for eukaryotic viruses, suggesting unique strategies and protein machinery might be needed to drive the process. In this light, one possibility is that the horseshoe-shaped lipid monolayer could serve as an intermediate equivalent to a single membrane leaflet in the hemi-fusion model.

Conclusion

The last decade has seen a major expansion in the level of high-resolution structures available for helical viruses. It is now clear that viral capsids with helical symmetry show multiple variations on several common themes. They may be rigid rods or flexible filaments composed of one or more parallel strands exhibiting either right- or left-handed twist, with open or capped ends, either naked or membrane enveloped. The protein subunits are often decorated 4-helix bundles, but subunits with 1 or 2 α -helices, and one or two domain subunits composed of larger helical bundles are also common. Nucleic acid is packaged independent of sequence, and can be bound within a single subunit or between subunits in successive helical strands, and may or may not share the same helical symmetry.

Despite recent progress, high-resolution structures of helical viruses are still scarce. Structural studies of the hemorrhagic *filoviridae*, including Marburg virus are clearly a priority. So too are studies of the *potyviridae*, *betaflexiviridae* or *closteroviridae*. These flexible plant viruses are of extreme agricultural importance and we lack high-resolution structural information for any member of these viral families. Recent structural studies of viruses infecting the Archaea also make clear that much remains to be learned about the origins, evolution and diversity of these viruses. Indeed, it seems each new high-resolution structural study identifies important new variations on the general themes described above, and in many cases reveals new architectural principles for the construction of viral capsids. Finally, high-resolution structural studies of the capping structures of helical viruses are generally lacking and sorely needed. These studies will certainly reveal further structural diversity among helical viruses and provide major insight into viral assembly, egress, maturation, attachment and entry. In short, much remains to be done, but recent advances in cryo-EM methodology clearly suggest that these are tractable problems and this structural information is now within reach.

Glossary

Megavirales A proposed taxon (order) to comprise all nucleocytoplasmic large DNA viruses, given its hypothetical common origin.

MIMIVIRE A hypothetical mimivirus defense system against virophage infection.

Polintovirus Large DNA transposons found in cellular organisms that encodes up to 10 proteins, including a homolog of viral capsid, possibly generating infectious particles.

Provirophage A virophage genome integrated in the host (giant virus) DNA.

Transpoviron Named after the “transposon,” this is a small linear plasmid-like DNA element found in mimivirus genomes.

Viral factory A viral-induced region in the host cytoplasm, wherein genome replication and viral morphogenesis of giant viruses occur.

Virophage A new family of viruses associated with giant viruses, depending on the viral host for replication.

Introduction

Viruses are traditionally perceived as filterable agents capable of passing through membranes with pore sizes of 0.22 μm , containing small genomes encoding only a few proteins. However, with the discovery of giant viruses, these concepts have been broken down, and a new era of virology has arisen. Giant viruses are part of a group of nucleocytoplasmic large DNA viruses (NCLDV), in which the viral particle size and structure and the genome length and complexity make them special within the group. In the original NCLDV proposal, the group consisted of the viral families *Poxviridae*, *Asfarviridae*, *Iridoviridae* and *Phycodnaviridae*. These families are composed of viruses that contain large double-stranded DNA (dsDNA) genomes, which replicate partially or entirely in the host cytoplasm, and which also share genetic similarities that points to a hypothetical common origin, thus comprising a monophyletic group. However, NCLDV only became a more intense topic of discussion and evolutionary study in 2003, due to the discovery of the first giant virus of amoebae named *Acanthamoeba polyphaga* mimivirus (APMV). Phylogenetic analyses indicated that APMV could be categorized with other viruses belonging to the NCLDV group, and the fact that this virus occupied an isolated branch in the phylogenetic tree that was associated with distinct morphological features led to the establishment of a new family, named *Mimiviridae*. The discovery of mimiviruses paved the way for the isolation of other giant viruses, with the development of new isolation techniques that were no longer constrained by the classical definitions of viruses based on particle size. As a consequence, new NCLDV members were discovered, including marseilleviruses, faustoviruses, pandoraviruses, cedratviruses, pithoviruses, orpheovirus, mollivirus, pacmanvirus and kaumoebavirus and new definitions of viruses are currently being debated. These viruses exhibit many distinctive features, along with some common characteristics that classify them as part of the NCLDV group, which was proposed to comprise a new viral order named “Megavirales.” In this article, we describe how the giant viruses were discovered and describe the basic features of this expansive group, including their diversity, replication cycles, genomics and evolution. Finally, we outline their genetic mobilome, including virophages, the parasites of giant viruses.

The Serendipitous Discovery of Giant Viruses of Amoebae

The isolation of the first mimivirus accidentally occurred during studies of amoebae-associated pathogens from environmental water samples in the midst of a pneumonia outbreak in Bradford, England. This virus was initially considered to be a bacterium infecting amoebae, mainly due to its Gram-positive staining back in 1992 that revealed a microorganism referred to as “Bradford coccus.” In addition, molecular attempts had failed to identify the new isolate. It was years later, when the sample was taken to Aix Marseille University where it was characterized and described in 2003 as the largest virus known at that time. Its classification as a virus was confirmed by the observation of the eclipse-phase during its replication and the visualization by transmission electron microscopy (TEM) of a likely isometric particle, which is typical of viruses, that was covered with long fibrils. The virus was named after its ability to mimic microbes and the host cell it was first isolated from, *Acanthamoeba polyphaga*. Mimivirus particles measure about 750 nm in diameter and are composed of a peculiar structure, characterized by a protein capsid containing an internal lipid membrane and surrounded by a dense glycoprotein fibril layer that is important for viral attachment to the host cell and other microorganisms (Fig. 1(A)). The capsid does not exhibit the typical icosahedral symmetry, presenting instead a modified vertex in starfish shape, named *stargate*, a portal from where the viral genome is released into the hosts’ cytoplasm (Fig. 1(B)). Its genome consists of a long linear double-stranded DNA molecule of approximately 1.2 Mbp, encoding over 1000 genes with many different

Fig. 1 Electron microscopy images of mimivirus particles. (A) Transmission electron microscopy image demonstrating the capsid covered in fibrils and an internal membrane; (B) scanning electron microscopy image evidencing the stargate structure.

functions, such as enzymes involved in DNA replication, recombination and repair (e.g., DNA polymerase and DNA topoisomerase), transcription (RNA polymerase and mRNA capping enzyme) and translation (translation factors and aminoacyl-tRNA synthetases), among others. The mimivirus particles penetrate into the host cell (free-living amoebae) by phagocytosis; this leads to rounding of the infected cell due to cytopathic effects, followed by lysis of the amoebae. Similar to other viruses belonging to the NCLDV group, mimiviruses replicate in the cytoplasm of the host cell, where they form large viral factories.

Since the discovery of APMV in the context of pneumonia, discussions about the possible relationship between mimiviruses and this disease have been raised. One study showed that laboratory mice inoculated intracardially with mimivirus displayed histopathologic symptoms, and mimiviruses were re-isolated from lung samples of these animals. Moreover, patients with pneumonia presented antibodies against mimivirus, and a high positivity of mimivirus in hospital facilities was recorded. Years later, the isolation of mimivirus from stool and bronchoalveolar lavage samples from patients with pneumonia strengthened the relationship between mimiviruses and this disease. However, human cells capable of being infected by these viruses, wherein the virus could establish a productive replication cycle, have not been found yet. Recent studies found no evidence of mimivirus replication in human peripheral blood mononuclear cells, despite its ability to enter and interfere with antiviral responses. Furthermore, other studies revealed the absence of mimiviruses in patients with respiratory disease by means of molecular biology and/or serology. However, it is important to consider the possibility that mimivirus might be a member of the vertebrates' virome, since their genome has been detected in humans, as well as both in domesticated and wild mammals. Nonetheless, this association needs more evidence to be confirmed. It is worth noting that a mimivirus-related virus infecting sturgeons has been described in the last years, causing lethal disease in the integumentary systems of these animals. Further studies are required to better evaluate the putative pathogenic role of mimiviruses and other giant viruses in humans and other vertebrates.

Diversity and Distribution of Giant Viruses in the World

After the discovery of mimiviruses, other giant viruses of amoebae have been described over the past decade in different places around the world, revealing an increasing complexity of this fraction of the virosphere. These viruses have a great structural diversity, with particles of different sizes and shapes, ranging from icosahedral capsids of about 200 nm to spherical, ovoid or tail-containing particles that exceed 1000 nm in length. Four distinct groups, named marseilleviruses (family *Marseilleviridae*), kaumobavirus, pacmanvirus and faustovirus (all phylogenetically related to *Asfarviridae* members), are composed of smaller viruses that present icosahedral capsids of 175–250 nm. Marseilleviruses were the second group of amoeba viruses to be discovered and were associated with *Acanthamoeba* cells in water samples from Paris, France. Over the years, other isolates were described, expanding the new viral family that is currently composed of five different lineages (A–E), with viruses discovered in different regions of the planet, such as Brazil, Australia, Tunisia and Japan, among others. The other groups, despite infecting amoeba cells, are most closely related to the African swine fever virus, a mammalian parasite. Pacmanvirus also infects *Acanthamoeba* cells, but kaumobavirus and faustoviruses are associated with *Vermamoeba vermiformis* cells, a different amoebal host. Similar to mimiviruses, these smaller viruses seem to have an internal lipid membrane surrounding their genetic material. Electron microscopy images demonstrate an overall similar structure between these different viruses (Fig. 2(A,B)). Although in-depth structural analyses of giant virus particles are scarce, some studies have revealed that certain viruses display exclusive features. Among them, faustovirus has the peculiarity of being formed by double concentric icosahedral capsids that connect to each other by protrusions of the internal capsid surface, which was not observed for other giant viruses until now.

Fig. 2 Diversity of giant viruses. Transmission and scanning electron microscopy images of different viral groups, representing the large variety of particle sizes and shapes among giant viruses. (A) mimivirus; (B) marseillevirus; (C) pandoravirus; (D) cedratvirus; (E) orpheovirus; (F) tupanvirus.

Other groups have larger particles that are ovoid in shape. In 2013, the description of pandoraviruses set a new limit to the viral particles' sizes, with ovoid-shaped virions with 1.0 μm presenting an ostiole-like apex at one end of its capsid (Fig. 2(C)). These viruses were first isolated in Chile, Australia and Germany, but novel isolates have been found in France, New Caledonia and Brazil, constituting an expanding putative *Pandoraviridae* family. Curiously, the pandoravirus capsid composition remains unknown, since no protein even remotely similar to the major capsid protein (MCP) was detected in the genomes of these viruses. A year later, the previous size limit was pushed once again by the discovery of the giant Pithovirus sibericum, isolated from 30,000-year-old permafrost soil samples from Siberia, composed of ovoid particles reaching more than 1.5 μm in length, making them the largest viral particles known so far. The particles have a striated capsid wall and a hexagonal grid-like structure, called a cork, which is generally found at one extremity of the particle and is an analogous structure to the apex of pandoraviruses. Curiously, a new virus was isolated from the same ancient sample, named Mollivirus sibericum, which is a spherical-shaped virus that is approximately 600 nm in diameter, but no further characterization of this virus has been performed to date. A contemporary pithovirus, named Pithovirus massiliensis, was isolated in France that exhibited a similar structure and a genomic conservation. Due to these structurally and genomically distinct features, a new viral family called "*Pithoviridae*" was suggested. In 2016, cedratvirus, a virus with a morphology similar to the pithovirus, was described, but it contained smaller particles with a mean size of 1.2 μm . Like the pithovirus, cedratvirus has apical corks, but at both ends of the particles. Other cedratviruses have been isolated in France and Brazil, with the Brazilian isolate exhibiting differences in particle and genome size and probably constituting a new lineage among cedratviruses (Fig. 2(D)). Cedratviruses and pithoviruses are phylogenetically close and might constitute a new single family. A distantly related *Pithoviridae* member named Orpheovirus was recently isolated using *V. vermamoeba* cells, which is morphologically similar to pandoraviruses, however, have more electron-dense capsid layers that are covered with short fibrils on their outer surface (Fig. 2(E)). More studies should be performed to get a clear picture of the diversity and distribution of these new giant viruses.

Currently, the family *Mimiviridae* encompasses the largest number of representatives, which have considerable differences in both structure and genomic features. After the discovery of APMV, several other mimivirus-like viruses were isolated from different parts of the world that exhibited structural similarities, but with genomic differences, contributing to the formation of three different lineages, informally called lineage A (represented by APMV), B (represented by Moumouvirus) and C (represented by Megavirus). Distantly related mimiviruses were also described infecting marine flagellates, namely, Cafeteria roenbergensis virus (CroV). CroV exhibits large particles with many genes shared with mimiviruses, which placed it within the family *Mimiviridae*, albeit within a separate genus, the *Cafeteriavirus*. The Bodo saltans virus, a kinetoplastid-infecting virus, constitutes a new member of the family, the first isolated member of the putative subfamily "*Klosneuvirinae*", whose members were initially identified by metagenomics analysis, revealing a new group of mimiviruses with unexpected genomic features, such as a much larger translation-related gene set. More recently, the structural and genomic complexity of the family was expanded with the discovery of Tupanviruses in samples collected from extreme places in Brazil, which are the viruses with the most complete translational apparatus in the virosphere. The viral particles are formed by a capsid similar to that of APMV and are associated with a cylindrical

tail of about 550 nm in length and 450 nm in diameter, with the whole particle covered in fibrils (Fig. 2(F)). The size of these particles is approximately 1.2 μm on average, although some particles may be up to 2.3 μm , due to the plasticity of the tail. Moreover, a new mimivirus-like parasite was isolated from the bark of a sycamore tree using *Saccamoeba* sp. as a host organism, referred to as Mimivirus KSL-5, exhibiting polyhedral virions of ~ 450 nm. Curiously, this virus was able to infect only *Saccamoeba* cells, suggesting the existence of a new group of mimiviruses with a novel host range.

The discovery of the first viruses associated with amoebas at the beginning of 21st century, with their diverse and complex structural characteristics, led to an intense search for new giant viruses in distinct places around the world. Since then, the number of new isolates has grown every year. These viruses have already been isolated using samples collected on each continent from various conditions, such as polluted environments, those with extreme conditions of temperature and pH, slightly anthropized regions and clinical samples. The constant discovery of giant viruses in wide-ranging types of samples reinforces the idea that these viruses are ubiquitous, as well as their protist hosts. Metagenomic studies reinforce their ubiquity, further indicating that many amoeba-related viruses have yet to be discovered. Remarkably, a large metagenomic analysis of soil samples from the Harvard forest (Massachusetts, USA) led to the assembly of the complete genomes of 16 new giant viruses, representing new lineages of klosneuviruses, other members of the family *Mimiviridae* and hundreds of MCP fragments belonging to giant viruses, thus indicating a huge diversity of these viruses in soil ecosystems that remains to be characterized. The host spectrum for most of these viruses is restricted to a few species of amoebae of the genus *Acanthamoeba* and/or *Vermamoeba*. However, recent discoveries of new members of the *Mimiviridae* family have shown that the spectrum may be broader, since they can infect different hosts, including other groups of protozoa and fish species (e.g., Bodo saltans virus, tupanviruses and namao virus). Novel studies involving exploration in unexplored regions using different cell platforms and isolation techniques could reveal exciting new viral groups, contributing to an increase in our knowledge about the diversity, ecology and evolution of these viruses.

The Life Style of the Giants

The replication cycle of giant viruses begins with viral entry into the host cells. For most of these viruses, this process has been proposed to occur by phagocytosis. Drugs such as cytochalasin, a phagocytosis inhibitor, have already been used to demonstrate the impact on this entry mechanism for mimivirus, cedratvirus and large membranous vesicles containing marseillevirus particles. For pandoravirus, pithovirus, mollivirus, orpheovirus, faustovirus, pacmanvirus and kaumoebavirus, entry by phagocytosis was suggested by electron microscopy image analyses. The phagocytosis process requires the recognition of particles of at least 500 nm, so the assumption that giant viruses enter by this mechanism seems reasonable. However, other smaller viruses, such as marseilleviruses (~ 250 nm) do not fulfill this criterion; thus, other mechanisms are likely involved. A thorough investigation of the replication cycle of this virus demonstrated that it is able to penetrate into cells by two alternative routes: by phagocytosis of grouped particles inside giant vesicles, or by exploiting other endocytic pathway for single particles. It is not clear yet if a similar process could occur for other large (yet not giant) viruses, such as faustoviruses and kaumoebavirus. After entry, the viral genome is released into the host cytoplasm. It has been observed that the uncoating process of mimivirus, mollivirus, pandoravirus, pithovirus, faustovirus and cedratvirus occurs after the fusion of the inner viral membrane with the endosomal membrane, allowing the formation of a channel through which the genome is released into the host cell. For other giant viruses, the uncoating process has not been described in detail yet. Mimiviruses release their genomes after stargate opening, and it was verified that endosome acidification is important for the induction of this step. The genomes of pandoraviruses, orpheovirus, pithovirus and cedratvirus are released by their respective ostiole-like apex and corks at the extremities of the particles.

Following the release of the genome, a typical viral eclipse phase is observed, wherein no viral particles are detected in the host cytoplasm, followed by the formation of small viral factories (VFs) in the cytoplasm. Throughout the infection, these VFs increase in size and occupy a large portion of the cellular cytoplasm in the later stages of infection. VFs of most giant viruses are non-delimited electron-lucent areas that contain particles at different stages of morphogenesis. Nevertheless, mimivirus VFs are well-defined structures, with at least two areas described: the central area, where replication of the genome and assembly of the structures necessary to form the viral capsid occurs, and a less electron-dense region of apparent fibrillar nature in the periphery. This outermost portion was named the fibrils acquisition area, since it was observed that is in this region the newly formed particles acquire the fibrils. Such compartmentalization of VFs was not observed for other giant viruses so far. Previous studies proposed that capsid morphogenesis of mimiviruses, pandoraviruses and cedratvirus is initiated by crescent-shaped lamellar structures that can be observed inside the VFs. The morphogenesis of cedratvirus involves crescent-shaped structures that assume staple-shaped and horseshoe conformations, depending on the section of TEM. Initially, only one of the corks is observed; then the capsid is filled and closed with the emergence of the second cork, and the capsid wall becomes thicker. Regarding pandoravirus, the capsid and internal contents seem to be assembled simultaneously. A pattern of where the assembly of the particle begins was not observed, since it can be at the extremity that presents ostiole-like apex or at the opposite end. For mimiviruses, capsid precursors increase in complexity and assume a pseudo-icosahedral symmetry. Then genome acquisition occurs at the stargate on the opposite side, and this step may occur simultaneously with the acquisition of surface fibrils.

During the morphogenesis step, defective particles have been recurrently observed for different groups of viruses, including mimiviruses, pandoraviruses, cedratviruses, among others. For mimiviruses, these unusual particles were initially associated with

Fig. 3 Representative scheme of the amoeba giant viruses replication cycle. The particles can enter host cell by phagocytosis or endocytosis for individual particles of marseillevirus (i). Subsequently, the genome is released into the host cytoplasm (ii). A viral factory is established in the cytoplasm of the host cell (iii) wherein the genome replicates (iv) and the morphogenesis of new particles occurs (v). During morphogenesis of mollivirus and pandoravirus, nuclear morphological changes are observed. The cycle ends with the release of progeny, which can occur by exocytosis or after cell lysis (vi). In this illustration, the pandoravirus was chosen in a representative way among the other groups of giant viruses. *Mimivirus viral factories organization is different from that illustrated in the figure, being more electron-dense than the cytoplasm and divided into at least two distinct areas.

the presence of virophages, parasites of giant viruses (described later in this article). However, recent analysis demonstrated the formation of defective particles, even in the absence of these parasites, thus, making clear that malformed particles are a natural process during the replicative cycle of these viruses. Once viral particles are fully assembled, release of most of these viruses occurs after cell lysis. Marseillevirus can release many particles into giant vesicles after cell lysis, which boosts its entry into another host cell by exploiting different entry strategies. Moreover, it has been suggested that the exocytosis process could be used for releasing mollivirus, pandoravirus, orpheovirus and cedratvirus particles. However, the viral release through exocytosis still needs to be further investigated for the majority of these viruses. The real impact of this viral release mechanism is still not well known.

Overall, in spite of some peculiarities of each viral group, a general picture of the replication cycle of giant viruses comes to light (Fig. 3). Viruses enter host cells through endocytosis or phagocytosis (i), release the genome into the cytoplasm (ii), establish a viral factory (iii) where the genome is replicated (iv), new particles are assembled during the morphogenesis step (v), and finally, the new progeny is released by cell lysis or exocytosis (vi). It is still not clear if these viruses depend on the host nucleus to complete their replication cycle, but some evidence for this has been described for marseilleviruses, pandoraviruses, mimivirus and mollivirus. Additional analyses are needed to better elucidate this important step of the life cycle for the different groups of giant viruses.

Genomics and Proteomics of Giant Viruses

A striking feature of giant viruses is the presence of an extensive dsDNA genome containing hundreds of genes. Some viruses have a linear genome, such as mimiviruses, tupanviruses, pandoraviruses, mollivirus and pacmanvirus, while others have a circular genome, such as marseilleviruses, faustoviruses, kaumobebavirus, pithoviruses, cedratviruses and orpheovirus. For the most part, the genome of these viruses is A/T-rich, ranging from ~55% in marseillevirus to ~75% in mimiviruses. Pandoravirus and mollivirus differ from the others in this regard, presenting genomes with G/C content above 60%. The size of the genome varies among the different viral groups between, ~350 kb and ~2500 kb, with Pandoravirus salinus containing the largest viral genome described so far. These viruses present, on average, 1 gene/kb and short intergenic regions of approximately 200 nucleotides, although large regions of thousands of nucleotides can occur between genes.

Even more impressive than the size of the genome is the genetic content of these viruses. Sequencing of the APMV genome in 2004 revealed the presence of genes rarely found in the virosphere, some of which are considered exclusive to the cellular world. Giant viruses present several genes involved in DNA replication, recombination and repair, nucleotide and carbohydrate metabolism, transcription (including RNA polymerases and various transcription factors) and protein synthesis. In the latter category, members of the family *Mimiviridae* are characterized by exhibiting several transfer RNAs (tRNAs), many translation factors (involved in the three stages of the process, i.e., initiation, elongation and release) and aminoacyl-tRNA synthetases (aaRS), which are key enzymes in the process of protein synthesis and have never been observed before for other viruses. In this context, the tupanviruses are the viruses that present the largest arsenal of genes involved in the translation processes observed in the virosphere, with up to 70 tRNAs and 20 aaRS (one for each proteinogenic amino acid encoded by the standard genetic code). Other giant viruses also have components of the translational apparatus, but in smaller quantity and diversity. Although several translation-related genes exist in these viruses, no ribosomal RNA (rRNA) gene has been detected in a virus thus far, making them still dependent on their hosts to synthesize proteins. In spite of several gene novelties observed, a common feature in all giant viruses at the time of their discovery is the large number of genes with unknown functions, without any similarity to other genes deposited in databases, called ORFans, with values varying from 31% to 84% of ORFans in the genome. Pandoravirus salinus has the larger fraction of ORFans among the giant viruses (Fig. 4). This massive number of new genes reflects how different these viruses are and suggests that they are a valuable source of genetic diversity.

Little is known about the transcriptional profile of these viruses and how the regulation of gene transcription occurs. Conserved A/T-rich sequences were identified in most of the mimivirus, marseillevirus, faustovirus and kaumobebavirus genes. Analyses based on RNA sequencing for APMV indicated the existence of a temporal profile of gene expression, with the AAAATTGA promoter sequence being associated with early expressed genes. Other members of the family *Mimiviridae* exhibit the same promoter motif, such as CroV, Bodo saltans virus and tupanvirus, which suggests it being a typical feature of this viral family. Marseillevirus also has genes expressed at different times in the replication cycle, but the previously identified motif promoter (AAATATTT) does not appear to be specifically related to any temporal class of genes, as is observed for mimiviruses. Most genes involved in cell signaling (e.g., serine/threonine kinases) and DNA replication and repair (e.g., DNA polymerase and DNA topoisomerases) are expressed at earlier times in the viral replication cycle, whereas transcription, translation and especially those involved in viral morphogenesis, such as constituents of the capsid (e.g., MCP and DNA packaging ATPase), are expressed later during the infectious cycle. In addition, transcripts of these viruses are polyadenylated, and hairpin polyadenylation signals have been identified throughout the genome of the mimivirus; however, there is still no information for the other giant viruses, being a broad field for new investigations.

Proteomics studies have revealed that giant virus particles are composed of a large amount of proteins, with more than 100 proteins found in the particles of APMV, CroV, Tupanvirus soda lake, Pithovirus sibericum, Mollivirus sibericum, pandoraviruses and E12 faustovirus. In the particles of all these viruses proteins with different functions were detected that were involved in DNA replication, oxidative pathways, lipid modification, transcription processes, in addition to the already expected structural genes. It is worth noting that in all viral particles, products from some ORFans were also identified, demonstrating that new genes discovered in these entities are truly expressed and translated, although their exact function remains unknown. Many genes identified in viral particles, as well as others expressed during the viral replication cycle, have multiple origins (i.e., from viruses, eukaryotes, bacteria and archaea), making giant DNA virus true genetic mosaics. This feature is observed in all groups of giant viruses discovered so far (Fig. 4). This genomic mosaicism is attributed in large part to the sympatric lifestyles of these organisms (i.e., from the same environment as several other microorganisms), since they infect amoebas, which are considered to be melting pots for the emergence of new organisms.

Origin and Evolution: An Intriguing Enigma

Giant amoeba viruses share several genes with other members of the NCLDV group, which is a possibly monophyletic group within the virosphere. With the discovery of different viral groups, the amount of so-called core genes has been drastically reduced, with only three genes currently present in members of all viral groups, including the D5 primase-helicase, viral late transcription factor 3 (VLTf3) and DNA polymerase B family. Some core genes appear to have been lost in some specific groups throughout evolution, such as the MCP genes in pandoravirus and DNA packaging ATPase in pithovirus and cedratvirus. Phylogenetic analyses based on these core genes tend to maintain the same topology, with the presence of three major clades, with the different groups of amoeba viruses scattered among them (Fig. 5). Although they share a common ancestor with the other *Megavirales* members, it is

Fig. 4 Genome composition of giant viruses. Pie-chart representing the proportion of genes presenting no homology in databases (ORFans) and genes with the best hits with eukaryotes, prokaryotes and viruses for different groups of giant viruses. The data was considered at the time the first isolate for each group was described. Representatives include Cedratvirus A11, Pacmanvirus A23, Orpheovirus LCC2, Mollivirus sibericum, Marseillevirus T19, Pithovirus sibericum, Faustovirus E12, Kaumoebavirus isolate Sc and Pandoravirus salinus.

possible that the gigantism observed for some groups has arisen independently throughout evolution, with the host acting as a selection agent of this characteristic. However, the origin and evolution of these viruses are at the heart of a heated debate that has lasted more than a decade, and there is still no scientific consensus.

The discovery of the presence of an extensive genome (> 1.0 Mb) encoding hundreds of proteins (~ 1000) in mimiviruses, with particular attention to translation genes like aaRS, contributed to reviving a long-standing debate about the nature of viruses (i.e., whether they are living organisms or not). Initial analyses suggested that mimiviruses could be remnants of a fourth domain of life, originating from a more complex organism (possibly a cell), which would have evolved through genomic reduction to adapt to the intracellular parasitism lifestyle. Additional phylogenomic analyses, associated with phylogenetic reconstructions based on protein fold conservation, reinforced this initial hypothesis, even inferring that giant viruses would have coexisted with primitive cellular life forms. However, alternative analyses involving conserved genes, as well as those related to the translation process, suggested an opposite scenario, in which the giant viruses would have originated from simpler entities and which would expand the genome mainly through gene gain and duplication. These analyses used sequence sampling and varied methods of phylogenetic reconstruction and have indicated that the evolution of these viruses would have followed an accordion-like model, where there were losses and gains of genes along the process of evolution. A positive balance of this relation would have occurred, resulting in viruses with extensive genomes and giant particles. Thus, the two opposite scenarios are in force and are constantly debated among specialists.

The accordion hypothesis has gained support from comparative analyses of Polintons/polintoviruses, a superfamily of virus-like DNA transposons commonly identified in the genome of eukaryotes and which have genes homologous to some giant virus

Fig. 5 Phylogeny of NCLDV. Phylogenetic reconstruction based on amino acid sequences of DNA polymerase B family of different members of NCLDV group. Viral families containing viruses not associated with amoebae were collapsed. Different colors represent distinct groups of amoebae giant viruses. Blue: mimiviruses, green: pandoraviruses and mollivirus, red: marseilleviruses, orange: pithoviruses, purple: asfarviridae-related viruses. Alignment was performed using MUSCLE, and the tree was built using the Maximum Likelihood method in FastTree software with 1000 bootstrap replicates. Only bootstrap values > 50 are shown. Scale bar represents rate of evolution.

genes, including those encoding the major capsid protein, the genome packaging ATPase and the virion maturation protease conserved in most NCLDVs. Recent analyses have suggested these mobile elements are the ancestors of NCLDVs, hence the various groups of giant amoeba viruses. These elements form a complex network of evolutionary interactions together with transpovirons and proviophages, elements that are part of the giant virus mobilome, something never before observed in other viruses.

Parasites of Viruses: The Nature of Virophages and the Genetic Mobilome

A hallmark of giant viruses is the presence of their own genetic mobilome, which includes introns, transposable elements and even viruses, which are the so-called virophages. Virophages are a new group of viruses associated with giant viruses, the first isolate of

Fig. 6 Virophage characteristics. (A) Transmission electron microscopy images of the Rio Negro virophage, a sputnik-related virus associated with the Samba virus (*Mimiviridae*), showing the virion shape within vesicles (left image), and replication cycle inside viral factory (middle image), and effect on giant virus particles (right image). White arrows indicate defective particles. VF: Viral factory; (B) genome features of the Sputnik virus, the first virophage to be discovered, indicating the genome size, ORF position, GC content and skew, and the conserved genes found in members of the *Lavidaviridae* family; (C) phylogenetic reconstruction based on MCP gene of virophages. Colors represent the virophages identified by culture methods (red) and metagenomics methods (blue). Alignment was performed using MUSCLE and the tree was built using the Maximum Likelihood method in FastTree software with 1000 bootstrap replicates. Only bootstrap values > 50 are shown. Scale bar represents rate of evolution.

which was described in 2008 and was associated with the *Acanthamoeba castellanii* mamavirus, one of the mimivirus isolates. The smaller virus, called Sputnik virus, has icosahedral particles of 75 nm and a circular A/T-rich genome of 18 kb encoding 21 ORFs (Fig. 6(A,B)). This virus was initially observed to be associated with mimivirus fibrils and this was initially suggested to serve as the mode of virophage entry into amoebae cells. However, analyses based on other isolated virophages have suggested that penetration may also occur through clathrin-mediated endocytosis. These viruses replicate in the viral factory of the giant virus, hijacking the transcription machinery of the viral host (Fig. 6(A)). These viruses do not have their own RNA polymerase, and *in silico* analyses have demonstrated the presence of promoter motifs similar to those found in mimivirus, reinforcing the hypothesis that these viruses depend on the giant virus host to have their genomes transcribed, and subsequently, to form the new progeny. The fact that the presence of the associated virus causes the reduction of the multiplication of the giant virus by ~70%, coupled with other peculiar characteristics of these parasites, was suggested to differentiate them from the already known satellite viruses, leading to the proposal of a new category of viruses, the virophages.

In the years following the discovery of the first isolate, other virophages were isolated, such as the Mavirus that is associated with the *Cafeteria roenbergensis* virus, Sputnik 2, Sputnik 3, Zamilon and Rio Negro virus, and all were associated with different isolates of mimiviruses. Interestingly, Sputnik 2 was identified integrated into the genome of a host mimivirus (Lentille virus), which led to the introduction of the term “provirophage.” Recently, the presence of provirophages in the genome of a unicellular algae (*Bigelowiella natans*), whose genes are actively transcribed, has been described, and their presence has led to the hypothesis that they would act as a defense system against giant virus infection. Mavirus was found integrated in multiple sites of the genome of the protozoan *Cafeteria roenbergensis*, and its activation was observed upon CroV infection, which led to the generation of a progeny with subsequent cellular lysis. The newly produced virophages lead to the suppression of the giant virus replication and increased the survival of the cellular host community, reinforcing the hypothesis of an antiviral system triggered by the presence of a provirophage.

Interestingly, the Zamilon viroplage is able to replicate with mimiviruses from lineage B and C, but not when in the presence of viruses from lineage A. Extensive analysis of the genome of different mimivirus isolates revealed that members from lineage A contain the insertion of a repeated Zamilon sequence within an operon, which was named the “mimivirus viroplage resistant element” or

MIMIVIRE. This system is composed of interspaced, repeated virophage sequences, along with nuclease genes, in a way analogous to the CRISPR-Cas system found in prokaryotes. By silencing the MIMIVIRE genes and the repeat sequences, the mimivirus becomes susceptible to the virophage infection, which led to the proposition of a new nucleic-acid-based immunity system against virophage infection. An alternative explanation was further proposed, stating that the defense system is not CRISPR-like, but instead a protein interaction model would be responsible for the phenotype. Recently, a pivotal component in this system, the R354 gene of mimivirus encoding a nuclease, had its structure defined, with analysis evidencing that the viral nuclease is functionally similar to the Cas4 protein, thus providing additional evidence that the MIMIVIRE is a new innate immune defense system.

Several other virophages have had their genomes identified by means of metagenomic analyses in different places of the world, including Yellowstone lake virophages (1–7, USA), Organic lake virophage and Ace lake mavirus (Antarctic), and Dishui lake virophage and Qinghai lake virophage (China). Other virophage genomes and gene fragments have been recovered from metagenomics datasets from Lake Mendota and Trout Bog Lake (Wisconsin, USA), identified as “freshwater virophage candidate genus.” Moreover, virophages have also been identified in datasets from sheep rumen metagenomics, constituting a hybrid group of virophages and polintons (linear genomes with inverted terminal repeats and genes with a strong similarity to polinton genes), named “sheep rumen virophages.” Some of these virophages were associated with algae viruses, which would be responsible for controlling the dynamics between the virus and algae-host in the environment. These new viruses have a genome that ranges from 17 to 30 kb, encoding 16–34 ORFs and containing several genes without known functions, but also containing some conserved genes, such as the major and minor capsid proteins, protease and genome packaging ATPase, which are used as genetic markers for these viruses and for phylogenetic reconstructions (Fig. 6(C)). The presence of at least some of these genes, along with the association or dependence on viruses of the NCLDV group to fully replicate, characterize a virus as a virophage and are thus classified in the family *Lavidaviridae*, which currently includes the genera *Sputnikvirus* and *Mavirus*. Recently, a new putative virophage was discovered associated with a mimivirus infecting *Saccamoeba* cells, which seems to affect the replication of the giant virus host, but no genomic data are available to date. It is possible that this new virophage and others yet to be found constitute new taxa in the family *Lavidaviridae*.

Virophages and provirophages are part of the genetic mobilome of giant viruses. Along with these elements are the transpovirons, a linear sequence of 7 kb capable of integrating randomly into regions of the genomes of giant viruses, and which have been identified in different isolates of the three lineages of the genus *Mimivirus*. In addition, introns have already been detected in genes of different giant viruses, such as mimivirus and faustovirus, and together with inteins complete the known viral mobilome so far. Genomic analyses have indicated similarities between the mobile elements of giant viruses and polintons/mavericks, large transposable DNA elements found in various cellular organisms. Phylogenetic reconstructions suggest that virophages, as well as giant viruses, may have originated from polintoviruses, which constitute a complex network of evolutionary interaction.

Perspectives

Giant viruses and their parasites represent a new and vast field within virology. Since the discovery of the giant mimivirus, new viral groups have been described, constantly expanding our appreciation of the complexity of the virosphere as we know it, and making it necessary to advance the taxonomy of these viruses. New isolation techniques for subsequent viral characterization associated with metagenomic techniques have strongly contributed to the advancement of our understanding of this complex group of eukaryoviruses and their parasites. Finally, studies aimed at better understanding the biology of these viruses are necessary and may reveal new features that could be exploited from the biotechnological point of view, given the enormous genomic and structural variety presented by these viruses, and the singular features of these giants of the virosphere.

Glossary

(–)-sense RNA (minus-sense RNA) A virus with a single-stranded RNA genome of the opposite polarity ('sense') as mRNA.

(+)-sense RNA (plus-sense RNA) A virus with a single-stranded RNA genome of the same polarity ('sense') as mRNA.

Assembly The stage of replication during which all the structural components come together at one site in the cell and the basic structure of the virus particle is formed.

Attachment The binding of a virus particle to a specific receptor on the surface of a host cell.

Capsid A protein shell comprising the main structural unit of a virus particle.

Envelope A lipid membrane enveloping a virus particle.

Fusion protein The protein(s) on the surface of a virus particle responsible for fusion of the virus envelope with cellular membranes.

Gene expression An important stage of viral replication at which virus genetic information is expressed: one of the major control points in replication.

Genome replication The stage of viral replication at which the virus genome is copied to form new progeny genomes.

Matrix protein A structural protein of a virus particle which underlies the envelope and links it to the core.

Maturation The stage of viral replication at which a virus particle becomes infectious.

Molecular epidemiology The use of nucleotide sequence information to study the diversity and distribution of virus populations.

mRNA Messenger RNA, translated on ribosomes to produce proteins.

Nucleocapsid The core of a virus particle consisting of the genome plus a complex of proteins.

Penetration The stage of viral replication at which the virus genome enters the cell.

Polyprotein A long polypeptide encoding several mature proteins which are subsequently released by protease cleavage.

Receptor A specific molecule on the surface of a cell which is used by a virus for attachment.

Release The stage of viral replication at which virus particles escape the infected cell.

Tropism The ability of a virus to infect specific cell or tissue types.

Uncoating The stage of viral replication at which structural proteins are lost and the virus genome is exposed to the replication machinery.

Virions Structurally mature, extracellular virus particles.

Virus attachment protein The protein on the surface of a virus particle responsible for binding the receptor.

Unlike cellular organisms, which 'grow' from an increase in the integrated sum of their components and reproduce by division, virus particles are produced from the assembly of preformed components. Once manufactured, virus particles (virions) do not grow or undergo division. This alone makes the process of virus replication distinct from the growth of all other biological agents, and although the term 'grow' is sometimes used in the vernacular to refer to propagation of viruses, it is best to avoid this word when referring to the processes of virus replication.

Although this article will attempt to paint a general picture of the process of virus replication, the type of host cell infected by the virus has a profound effect on the replication process. There are many examples of viruses undergoing different replicative cycles in different cell types. However, the coding capacity of the genome determines the basic replication strategy used by different viruses. This strategy may involve heavy reliance on the host cell, in which case the virus genome can be very compact and need only encode the essential information for a few proteins, for instance, in parvoviruses. Alternatively, large and complex virus genomes, such as those of poxviruses, encode most of the information necessary for replication, and the virus is only reliant on the cell for the provision of energy and the apparatus for macromolecular synthesis, such as ribosomes. Viruses with RNA genomes have no apparent need to enter the nucleus, although during the course of replication, some do. DNA viruses, as might be expected, mostly replicate in the nucleus where host cell DNA is replicated and the biochemical apparatus necessary for this process is located. However, some viruses with DNA genomes (e.g., poxviruses) have evolved to contain sufficient biochemical capacity to be able to replicate in the cytoplasm, with minimal requirement for host cell functions.

Virus replication can be divided into eight stages, as shown in Fig. 1. It should be emphasized that these are arbitrary divisions, used here for convenience in explaining the replication cycle of a theoretical, 'typical' virus. Regardless of their hosts, all viruses must undergo each of these stages in some form to successfully complete their replication cycle. Not all the steps described here are detectable as distinct stages for all viruses; often they blur together and appear to occur almost simultaneously. Some of the individual stages have been studied in great detail and a considerable amount of information is known about them. Other stages have been much harder to study, and less information is available.

Fig. 1 Schematic overview of a generalized scheme of virus replication. Reproduced from Cann AJ (2004) *Principles of Molecular Virology*, 4th edn. Amsterdam: Elsevier, with permission from Elsevier.

Attachment

The attachment phase of replication comprises specific binding of a virus-attachment protein (or 'antireceptor') to a cellular receptor molecule. Virus receptors on cell surfaces may be proteins (usually glycoproteins) or carbohydrate residues present on glycoproteins or glycolipids. Some complex viruses (e.g., in the *Poxviridae* or *Herpesviridae*) use more than one receptor and therefore have alternative routes of uptake into cells. Most bacteriophage receptors are on the bacterial cell wall, although certain phages use cellular appendages (pili, flagella) as primary adsorption sites. Attachment is an automatic docking process and the kinetics of receptor binding are controlled by the chemical and thermodynamic characteristics of the molecules involved, that is, their relative concentrations and availability.

In most cases, the expression (or absence) of receptors on the surface of host cells determines the tropism of a particular virus, that is, the types of cell in which it is able to replicate. The attachment phase of infection therefore has a major influence on viral pathogenesis and in determining the course of a virus infection. Plant viruses must overcome different problems to animal viruses in initiating infection. The outer surfaces of plants are composed of protective layers of waxes and pectin, and each cell is surrounded by a thick wall of cellulose overlying the cytoplasmic membrane. No known plant virus uses a specific cellular receptor of the type that animal and bacterial viruses use to attach to cells and plant viruses must rely on mechanical breaks in the cell wall to directly introduce a virus particle into a cell.

Some virus receptors consist of more than one protein and multiple interactions are required for virus entry. An example of this is human immunodeficiency virus-1 (HIV-1), the primary receptor for which is the T-cell antigen, CD4. The binding site for the HIV-1 attachment protein (antireceptor), gp 120, has been mapped to the first variable region of CD4, although additional amino acids of the second variable domain also contribute toward binding. The sequences important for CD4 binding have also been mapped in gp120. Deletions in this region or site substitutions abolish CD4 binding. In addition to CD4, there is at least one accessory factor which is necessary to form a functional HIV-1 receptor. These factors have now been identified as a family of proteins known as β -chemokine receptors. Multiple members of this class of proteins have been shown to play a role in the entry of HIV-1 into cells, and their distribution in the body is the primary control for the tropism of HIV-1 for different cell types.

Occasionally, the specificity of receptor binding can be subverted by nonspecific interactions between virus particles and host cells. Virus particles may be taken up by cells by pinocytosis or phagocytosis. However, without some form of physical interaction which holds the virus particle in close association with the cell surface, the frequency of these events would be very low. In addition, the fate of viruses absorbed into endocytic vacuoles is usually to be degraded, except in cases where the virus particle enters cells by this route.

On occasion, binding of antibody-coated virus particles to Fc receptor molecules on the surface of monocytes and other blood cells can result in virus uptake. The presence of antiviral antibodies can result in increased virus uptake by cells and increased pathogenicity, rather than virus neutralization, as would normally be expected. The significance of such mechanisms *in vivo* is not known.

Entry

Entry of the virus particle into the host cell normally occurs a short time after attachment of the virus to the receptor. Unlike attachment, cell entry is generally an energy-dependent process, that is, the cell must be metabolically active for this to occur. Three main mechanisms are observed:

1. Translocation of the entire virus particle across the cytoplasmic membrane of the cell. This process is relatively rare among viruses and is poorly understood. It is mediated by proteins in the virus capsid and specific membrane receptors.
2. Endocytosis of the virus into intracellular vacuoles. This is probably the most common mechanism of virus entry into cells. It does not require any specific virus proteins (other than those already utilized for receptor binding) but relies on the normal formation and internalization of coated pits (term to be explained) at the cell membrane. Receptor-mediated endocytosis is an efficient process for taking up and concentrating extracellular macromolecules.
3. Fusion of the virus envelope (where present) with the cell membrane, either directly at the cell surface or following endocytosis in a cytoplasmic vesicle. Fusion requires the presence of a specific fusion protein in the virus envelope, for example, influenza A virus hemagglutinin or the transmembrane glycoproteins of retroviruses. These proteins promote the joining of the cellular and virus membranes which results in the nucleocapsid being deposited directly in the cytoplasm. There are two types of virus-driven membrane fusions: pH-dependent and pH-independent.

The process of endocytosis is almost universal in animal cells and requires the formation of clathrin-coated pits which results in the engulfment of a membrane-bounded vesicle by the cytoplasm of the cell. At this point, any virus contained within these structures is still cut off from the cytoplasm by a lipid bilayer and therefore has not strictly entered the cell. As endosomes fuse with lysosomes, the environment inside these vessels becomes progressively more hostile as they are acidified and the pH falls, while the concentration of degradative enzymes rises. This means that the virus must leave the vesicle and enter the cytoplasm before it is degraded. There are a number of mechanisms by which this occurs, including membrane fusion and rescue by transcytosis. The release of virus particles from endosomes and their passage into the cytoplasm is intimately connected with (and often impossible to separate from) the process of uncoating.

Uncoating

Uncoating describes the events which occur after host cell entry, during which the virus capsid is partially or completely degraded or removed and the virus genome exposed, usually still in the form of a nucleic acid–protein complex. Uncoating occurs simultaneously with or immediately after entry and is thus difficult to study. In bacteriophages which inject their genome directly into the cell, entry and uncoating are the same process.

The removal of a virus envelope during membrane fusion is the initial stage of the uncoating process for enveloped viruses. Uncoating may occur inside endosomes, being triggered by the change in pH as the endosome is acidified, or directly in the cytoplasm. Entry into the endocytic pathway is a hazardous process for viruses because if they remain in the vesicle too long, they will be irreversibly damaged by low pH or lysosomal enzymes. Hence, some viruses have evolved proteins to control this process; for example, the influenza A virus M2 protein is a membrane channel which allows entry of hydrogen ions into the nucleocapsid, facilitating uncoating. The M2 protein is multifunctional, and also has a role in virus uncoating. In the piconaviruses, penetration of the cytoplasm by exit of virus from endosomes is tightly linked to uncoating. The acidic environment of the endosome causes a conformational change in the particle at around pH 5 that reveals hydrophobic domains not present on the surface of mature virus capsids. These hydrophobic patches interact with the endosomal membrane and form pores through which the RNA genome passes into the cytoplasm of the host cell.

The ultimate product of uncoating depends on the structure of the virus genome/nucleocapsid. In some cases, the resulting structure is relatively simple; for example, piconaviruses have only a small basic protein of approximately 23 amino acids covalently attached to the 5' end of the RNA genome. In other cases, the virus core which remains is highly complex; for example, in the poxviruses uncoating occurs in two stages – removal of the outer membrane as the particle enters the cell and in the cytoplasm, followed by further uncoating as the core passes into the cytoplasm. In this case, the core still contains dozens of proteins and at least 10 distinct enzymes.

The structure and chemistry of the nucleocapsid determines the subsequent steps in replication. Reverse transcription can only occur inside an ordered retrovirus core particle and does not proceed to completion with the virus RNA free in solution. Eukaryotic viruses which replicate in the nucleus, such as members of the *Herpesviridae*, *Adenoviridae*, and *Polyomaviridae*, undergo structural changes following penetration, but overall remain largely intact. This is important because these capsids contain nuclear localization sequences responsible for attachment to the cytoskeleton and this interaction allows the transport of the entire capsid to the nucleus. At the nuclear pores, complete uncoating occurs and the nucleocapsid passes into the nucleus.

Transcription and Genome Replication

The replication strategy of a virus depends, in large part, on the structure and composition of its genome. For viruses with RNA genomes in particular, genome replication and transcription are often inextricably linked, and frequently carried out by the same enzymes. Therefore, it makes most sense to consider both of these aspects of virus replication together.

Group I: Double-Stranded DNA

This class can be further subdivided into two as follows:

1. Replication is exclusively nuclear or associated with the nucleoid of prokaryotes. The replication of these viruses is relatively dependent on cellular factors. In some cases, no virus-encoded enzymes are packaged within these virus particles as this is not necessary, whereas in more complex viruses numerous enzymatic activities may be present within the particles.
2. Replication occurs in cytoplasm. These viruses have evolved (or acquired from their hosts) all the necessary factors for transcription and replication of their genomes and are therefore largely independent of the cellular apparatus for DNA replication and transcription. Because of this independence from cellular functions, these viruses have some of the largest and most complex particles known, containing many different enzymes.

Group II: Single-Stranded DNA

The replication of these virus genomes occurs in the nucleus, involving the formation of a double-stranded intermediate which serves as a template for the synthesis of new single-stranded genomes. In general, no virus-encoded enzymes are packaged within the virus particle since most of the functions necessary for replication are provided by the host cell.

Group III: Double-Stranded RNA

These viruses all have segmented genomes, as each segment is transcribed separately to produce individual monocistronic messenger RNAs. Replication occurs in the cytoplasm and is largely independent of cellular machinery, as the particles contain many virus-encoded enzymes essential for RNA replication and transcription since these processes (involving copying RNA to make further RNA molecules) do not normally occur in cellular organisms.

Group IV: Single-Stranded (+)-Sense RNA

These viruses can be subdivided into two groups.

1. *Viruses with polycistronic mRNA such as flaviviruses and picornaviruses.* As with all the viruses in this group, the genome RNA represents mRNA which is translated after infection, resulting in the synthesis of a polyprotein product, which is subsequently cleaved to form the mature proteins.
2. *Viruses with complex transcription such as coronaviruses and togaviruses.* In this subgroup, two rounds of translation are required to produce subgenomic RNAs which serve as mRNAs in addition to the full-length RNA transcript which forms progeny virus genomes. Although the replication of these viruses involves copying RNA from an RNA template, no virus-encoded enzymes are packaged within the genome since the ability to express genetic information directly from the genome without prior transcription allows the virus replicase to be synthesized after infection has occurred.

Group V: Single-Stranded (-)-Sense RNA

The genomes of these viruses can also be divided into two types.

- *Segmented.* The first step in the replication of these viruses (e.g., orthomyxoviruses) is transcription of the (-)-sense RNA genome by the virion RNA-dependent RNA polymerase packaged in virus particles to produce monocistronic mRNAs, which also serve as the template for subsequent genome replication.
- *Nonsegmented.* Monocistronic mRNAs for each of the virus genes are produced by the virus transcriptase in the virus particle from the full-length virus genome. Subsequently, a full-length (+)-sense copy of the genome is synthesized which serves as a template for (-)-sense progeny virus genomes (e.g., paramyxoviruses and rhabdoviruses).

Group VI: Single-Stranded RNA with DNA Intermediate

Retrovirus genomes are composed of (+)-sense RNA but are unique in that they are diploid and do not serve directly as mRNA but as a template for reverse transcription into DNA. A complete replication cycle involves conversion of the RNA form of the virus genetic material into a DNA form, the provirus, which is integrated into the host cell chromatin. The enzyme reverse transcriptase needs to be packaged into virus particles to achieve this conversion, as virus genes are only expressed from the DNA provirus and not from the RNA genome found in retrovirus particles of retroviruses.

Group VII: Double-Stranded DNA with RNA Intermediate

This group of viruses also relies on reverse transcription, but unlike the retroviruses, this occurs inside the virus particle during maturation. On infection of a new cell, the first event to occur is repair of the gapped genome, followed by transcription. As with group VI viruses, a reverse transcriptase enzyme activity is present inside virus particles, but in this case, the enzyme carries out the conversion of virus RNA into the DNA genome of the virus inside the virus particle. This contrasts with retroviruses where reverse transcription occurs after the RNA genome has been released from the virus particle into the host cell.

Assembly

During assembly, the basic structure of the virus particle is formed as all the components necessary for the formation of the mature virion come together at a particular site in the cell. The site of assembly depends on the pattern of virus replication and the mechanism by which the virus is eventually released from the cell and so varies for different viruses. Although some DNA virus particles form in the nucleus, the cytoplasm is the most common site of particle assembly. In the majority of cases, cellular membranes are used to anchor virus proteins, and this initiates the process of assembly.

For enveloped viruses, the lipid covering is acquired through a process known as budding, where the virus particle is extruded through a cell membrane. Lipid rafts are membrane microdomains enriched in glycosphingolipids (or glycolipids), cholesterol and a specific set of associated proteins. Lipid rafts have been implicated in a variety of cellular functions, such as apical sorting of proteins and signal transduction, but they are also used by viruses as platforms for cell entry (e.g., for HIV-1, SV40, and the rotaviruses), and as sites for particle assembly, budding and release from the cell membrane (e.g., in influenza A virus, HIV, measles virus, and rotaviruses).

As with the earliest stages of replication, it is often not possible to identify the assembly, maturation, and release of virus particles as distinct and separate phases. The site of assembly has a profound influence on all these processes. In general terms, rising intracellular levels of virus proteins and genomes reach a critical concentration and this triggers assembly. Many viruses achieve high levels of newly synthesized structural components by concentrating these into subcellular compartments known as inclusion bodies. These are a common feature of the late stages of infection of cells by many different viruses. Alternatively, local concentrations of virus structural components can be boosted by lateral interactions between membrane-associated proteins. This mechanism is particularly important in enveloped viruses which are released from the cell by budding (see above).

Maturation

Maturation is the stage of the replication cycle at which virus particles become infectious. This often involves structural changes in the newly formed particle resulting from specific cleavages of virus proteins to form the mature products or from conformational changes in proteins which occur during assembly (e.g., hydrophobic interactions). Protein cleavage frequently leads to substantial structural changes in the capsid. Alternatively, internal structural alterations, for example, the condensation of nucleoproteins with the virus genome, often result in changes visible by electron microscopy.

Proteases are frequently involved in maturation, and virus-encoded enzymes, cellular proteases or a mixture of the two may be used. Virus-encoded proteases are usually highly specific for particular amino acid sequences and structures, only cutting a particular peptide bond in a particular protein. Moreover, they are often further controlled by being packaged into virus particles during assembly and only activated when brought into close contact with their target sequence by the conformation of the capsid, for example, by being placed in a local hydrophobic environment, or by changes of pH or cation cofactor concentrations inside the particle as it forms. Retrovirus proteases are good examples of enzymes involved in maturation which are under tight control. The retrovirus core particle is composed of proteins from the *gag* gene and the protease is packaged into the core before its release from the cell on budding. During the budding process, the protease cleaves the *gag* protein precursors into the mature products – the capsid, nucleocapsid, and matrix proteins of the mature virus particle. Other protease cleavage events involved in maturation are less closely controlled. Influenza A virus hemagglutinin must be cleaved into two fragments (HA₁ and HA₂) to be able to promote membrane fusion during infection. Cellular trypsin-like enzymes are responsible for this process, which occurs in secretory vesicles as the virus buds into them prior to release at the cell surface; however, this process is controlled by the virus M2 protein, which regulates the pH of intracellular compartments in influenza virus-infected cells.

Release

For lytic viruses (most nonenveloped viruses), release is a simple process – the infected cell breaks open and releases the virus. The reasons for lysis of infected cells are not always clear, but virus-infected cells often disintegrate because viral replication disrupts normal cellular function, for example, the expression of essential genes. Many viruses also encode proteins that stimulate (or in some cases suppress) apoptosis, which can also result in release of virus particles.

Enveloped viruses acquire their lipid membrane as the virus buds out of the cell through the cell membrane, or into an intracellular vesicle prior to subsequent release. Virion envelope proteins are picked up during this process as the virus particle is extruded. This process is known as budding. As mentioned earlier, assembly, maturation, and release are usually simultaneous processes for viruses which are released by budding. The release of mature virus particles from their host cells by budding presents a problem in that these particles are designed to enter, rather than leave, cells. Certain virus envelope proteins are involved in the release phase of replication as well as in receptor binding. The best-known example of this is the neuraminidase protein of influenza virus. In addition to being able to reverse the attachment of virus particles to cells via hemagglutinin, neuraminidase is also believed to be important in preventing the aggregation of influenza A virus particles and may well have a role in virus release. In addition to using specific proteins, viruses which bud have also solved the problem of release by the careful timing of the assembly-maturation-release pathway. Although it may not be possible to separate these stages by means of biochemical analysis, this does not mean that spatial separation of these processes has not evolved as a means to solve this problem.

Nomenclature

Ab	Antibody	IgSF	Immunoglobulin Superfamily
ACE2	Angiotensin-converting enzyme 2	IgV	Ig-like variable
Ad	Adenovirus	JAM-A	Junctional adhesion molecule-A
APN	Aminopeptidase N	JCPyV	JC polyomavirus
BKPyV	BK polyomavirus	LDLR	low density lipoprotein receptor
CAR	Coxsackievirus and adenovirus receptor	LSTa	Lactoseries sialyl tetrasaccharide a
CAV	Coxsackie A virus	LSTc	Lactoseries sialyl tetrasaccharide c
CCP	Complement control proteins	MERS	Middle east respiratory syndrome
CoV	Coronavirus	MV	Measles virus
cryo-EM	Cryo-electron microscopy	Neu5Ac	5-N-acetylneuraminic acid
DAF	Decay-accelerating factor	PtdSer	Phosphatidylserine
DPP4	Dipeptidyl peptidase 4	PV	Poliovirus
EBV	Epstein–Barr virus	PVR	Poliovirus receptor
EchoV	Echovirus	PyV	Polyomavirus
EV	Enterovirus	RBD	Receptor binding domain
GAG	Glycosaminoglycan	RCA	Regulators of complement activity
GalNAc	N-acetylgalactosamine	S	Spike
GlcNAc	N-acetylglucosamine	SARS	Severe acute respiratory syndrome
HBGA	Histo-blood group antigen	SCR	Short consensus repeats
HRV	Human rhinovirus	Sia	Sialic acid
HS	Heparan sulfate	SLAM	Signaling lymphocyte-activation molecule
ICAM-1	Intercellular adhesion molecule-1	TIM	Transmembrane, Immunoglobulin and Mucin domain

Glossary

Attachment factor Cell surface molecule that allows a virus to adhere to a cell, but it is dispensable for virus cell entry.

Entry receptor Cell membrane molecule necessary for virus penetration into cells and that participates in the virus cell entry process. Its expression makes a cell susceptible to virus infection.

Lipidome (virus) Set of lipids in a virus envelope membrane.

Metastable Refers to virus particles that are in a relatively high energy state, and capable of transitioning to more stable conformations.

Uncoating The process by which the virus genome exits from a virus particle to be transferred inside of the cell for its replication and generation of the virus progeny. Although it is commonly applied to non-enveloped viruses, virus-cell fusion can be considered an uncoating process.

Introduction

The majority of viruses have an extracellular phase in their life cycle, which is a necessary part of virus transmission and dissemination. Virus particles are metastable structures that transport the viral genome from cell to cell. To initiate the replication cycle for the production of progeny virions, the virus must first enter a cell. Cell entry is mediated by the specific interaction of the virus with molecules on the cell surface – the receptor – resulting in attachment, and the subsequent internalization of the virus particle, or the genome. A cell that expresses the cognate cell surface receptor for a virus is termed susceptible. However, not all susceptible cells to which the virus binds are capable of supporting infection and replication, perhaps due to the absence of necessary intracellular components. Therefore, cells that support virus binding, entry, replication, and progeny virion release are also termed permissive.

With certain notable exceptions, such as viruses of fungi that exhibit no extracellular stage in the life cycle or plant viruses introduced mechanically by insect vectors, the virus receptor is the primary determinant of virus tropism. The identification and

characterization of the receptor therefore provides important insights into the early stages of the virus life cycle, and has been a major research focus of molecular virologists worldwide.

Virus Receptors in Virus Cell Entry

Our enhanced understanding of virus–receptor interactions and the early events in cell entry have demonstrated that this process is, in many cases, considerably more complicated than originally thought, involving multiple cell-surface or intracellular molecules with different roles in the entry events. A classical definition of a virus receptor would be the cell-surface molecule that mediates virus attachment and cell entry. Virus receptor expression in a cell is necessary for virus infection. It should be distinguished from attachment factors, which are dispensable for cell entry and whose expression can enhance infection but it does not render a cell susceptible. Our current understanding of these processes demonstrates that many viruses use different molecules to mediate attachment and post-attachment entry events. For this reason, the term co-receptor is often used to indicate an accessory molecule implicated in cell membrane penetration. Some viruses can use several receptors for cell entry or evolve to use alternate receptors, which changes their tropism, facilitates host-to-host transmission and generates zoonosis.

Attachment

Viruses initially bind to cell surface receptors or attachment factors. Receptor binding is more virus-specific than binding to attachment factors. Numerous viruses attach to lectins using virus envelope carbohydrates or benefit from envelope phosphatidylserine (PtdSer) to bind to PtdSer-binding proteins. Nonetheless, virus–receptor interactions are determined by unique virus protein surfaces, which restrict receptor selection. Although highly distinct viruses can select common receptors, some of which are abundant on the cell surface, there is a large diversity in receptor usage due to differences in virus structures. In many viruses, receptor binding surfaces have low accessibility, which decreases their association binding rates and the monovalent affinity. Virus binding sites for glycan receptors are typically more surface-exposed, with low affinities that often lie in the millimolar range. In all cases, the presence of many identical binding sites on a virus allows for multivalent binding, and this can increase its avidity for the cell by several orders of magnitude.

Receptor-mediated virus uncoating
